A

REFERENCE HANDBOOK

OF THE

MEDICAL SCIENCES

EMBRACING THE ENTIRE RANGE OF

SCIENTIFIC AND PRACTICAL MEDICINE

AND

ALLIED SCIENCE

BY VARIOUS WRITERS

ILLUSTRATED BY CHROMOLITHOGRAPHS AND FINE WOOD ENGRAVINGS

EDITED BY ALBERT H. BUCK, M.D.
NEW YORK CITY

VOLUME VI.

NEW YORK
WILLIAM WOOD & COMPANY
56 & 58 LAFAYETTE PLACE

COPYRIGHT, 1888,
BY WILLIAM WOOD & COMPANY

LIST OF CONTRIBUTORS TO VOLUME VI.

CHARLES W. ALLEN, M.D....NEW YORK, N. Y.
Visiting Physician, Charity Hospital.

ADOLF ALT, M.D.................ST. LOUIS, MO.

EDMUND ANDREWS, M.D..........CHICAGO, ILL.
Professor of Clinical Surgery, Chicago Medical College; Visiting Surgeon, Mercy Hospital.

P. E. ARCHINARD, M.D.......NEW ORLEANS, LA.
Visiting Physician, Nervous Diseases Service, Charity Hospital; Assistant Pathologist to the same hospital.

I. EDMONSON ATKINSON, M.D..BALTIMORE, MD.
Professor of Pathology and Clinical Professor of Dermatology, University of Maryland.

JAMES B. BAIRD, M.D.............ATLANTA, GA.

FRANK BAKER, M.D.........WASHINGTON, D. C.
Professor of Anatomy, Medical Department of Georgetown University.

HENRY B. BAKER, M.D..........LANSING, MICH.
Secretary of the Michigan State Board of Health.

WILLIAM BARNES, M.D..........DECATUR, ILL.

ELIAS H. BARTLEY, M.D......BROOKLYN, N. Y.
Lecturer on Chemistry, Long Island College Hospital; Chemist to the Brooklyn Board of Health.

G. BAUMGARTEN, M. D............ST. LOUIS, MO.
Professor of Special Pathology and Therapeutics, St. Louis Medical College.

ALBERT N. BLODGETT, M.D........BOSTON, MASS.
Professor of Pathology and Therapeutics, Boston Dental College.

W. P. BOLLES, M.D.................BOSTON, MASS.
Professor of Materia Medica and Botany, Emeritus, at the Massachusetts College of Pharmacy; Visiting Surgeon, Boston City Hospital.

MEADE BOLTON, M.D.............BALTIMORE, MD.
Assistant in Bacteriology, Johns Hopkins University.

L. BREMER, M.D...................ST. LOUIS, MO.

NORMAN BRIDGE, M.D.............CHICAGO, ILL.
Professor of Pathology and Adjunct Professor of the Principles and Practice of Medicine, Rush Medical College.

EDWARD BENNET BRONSON, M.D..NEW YORK, N. Y.
Professor of Dermatology, New York Polyclinic; Visiting Surgeon, Charity Hospital.

DILLON BROWN, M.D..........NEW YORK, N. Y.
Assistant Surgeon, New York Orthopedic Dispensary and Hospital.

PETER H. BRYCE, M.D.........TORONTO, CANADA.
Professor of Chemistry, Ontario Agricultural College; Secretary of the Provincial Board of Health.

L. DUNCAN BULKLEY, M.D.....NEW YORK, N. Y.
Physician to the New York Skin and Cancer Hospital; Consulting Physician, Manhattan Eye and Ear Hospital.

WILLIAM N. BULLARD, M.D.......BOSTON, MASS.
Physician to the Nervous Department, Boston Dispensary; Visiting Physician, Carney Hospital.

FRANK BULLER, M.D........MONTREAL, CANADA.
Professor of Ophthalmology and Otology, McGill University.

J. WELLINGTON BYERS, M.D..CHARLOTTE, N. C.

ARTHUR T. CABOT, M.D...........BOSTON, MASS.
Attending Surgeon, Massachusetts General Hospital, Boston.

DONALD M. CAMMANN, M.D...NEW YORK, N. Y.
Instructor in Diseases of the Chest, New York Polyclinic; Visiting Physician, Orphans' Home and Asylum.

WILLIAM H. CARMALT, M.D..NEW HAVEN, CONN.
Professor of Surgery, Yale University; Visiting Surgeon, New Haven Hospital.

W. T. COUNCILMAN, M.D........BALTIMORE, MD.
Associate Professor of Pathological Anatomy, Johns Hopkins University.

EDWARD CURTIS, M.D.........NEW YORK, N. Y.
Professor Emeritus of Materia Medica and Therapeutics, College of Physicians and Surgeons, New York.

LESTER CURTIS, M.D...............CHICAGO, ILL.
Professor of Histology, Chicago Medical College; Visiting Physician, Mercy Hospital.

CHARLES LOOMIS DANA, M.D..NEW YORK, N. Y.
Professor of Diseases of the Mind and Nervous System, and of Medical Electricity, New York Post-graduate Medical School and Hospital; Visiting Physician, Bellevue Hospital.

N. P. DANDRIDGE, M.D..........CINCINNATI, O.
Professor of Genito-urinary and Venereal Diseases, Miami Medical College.

N. S. DAVIS, M.D...................CHICAGO, ILL.
Professor of the Principles and Practice of Medicine and of Clinical Medicine, Chicago Medical College; Visiting Physician, Mercy Hospital.

ROBERT H. M. DAWBARN, M.D..NEW YORK, N. Y.
Examiner in Surgery, College of Physicians and Surgeons, New York; Visiting Physician, Northwestern Dispensary, Department of Diseases of Children.

D. BRYSON DELAVAN, M.D....NEW YORK, N. Y.
Professor of Laryngology and Rhinology, New York Polyclinic; Chief of Clinic, Department of Diseases of the Throat, College of Physicians and Surgeons, New York.

W. S. DENNETT, M.D..........NEW YORK, N. Y.
Assistant Surgeon, Ophthalmic Department, New York Eye and Ear Infirmary.

JAMES H. ETHERIDGE, M.D.......CHICAGO, ILL.
Professor of Materia Medica and Medical Jurisprudence, Rush Medical College.

WILLIAM H. FLINT, M.D......NEW YORK, N. Y.
Attending Physician, Presbyterian Hospital; Assistant to the Chair of Principles and Practice of Medicine, Bellevue Hospital Medical College.

WILLIAM H. FORD, M.D......PHILADELPHIA, PA.
President of the Philadelphia Board of Health.

EUGENE FOSTER, M.D.............AUGUSTA, GA.
President of the Board of Health of Augusta.

GEORGE B. FOWLER, M.D....NEW YORK, N. Y.
Professor of Physiological Chemistry, New York Polyclinic; Visiting Physician, New York Infant Asylum.

SIMON H. GAGE, B.S...............ITHACA, N. Y.
Assistant Professor of Physiology, and Lecturer on Microscopical Technology, Cornell University.

WILLIAM GARDNER, M.D....MONTREAL, CANADA.
Professor of Gynecology, McGill University; Gynecologist to the Montreal General Hospital.

GEORGE W. GAY, M.D.............BOSTON, MASS.
Visiting Surgeon, Boston City Hospital.

H. GRADLE, M.D....................CHICAGO, ILL.
Professor of Physiology, Chicago Medical College.

JAMES E. GRAHAM, M.D.......TORONTO, CANADA.
Lecturer on Diseases of the Integumentary System, Toronto School of Medicine.

JOHN GREEN, M.D................ST. LOUIS, MO.
Professor of Ophthalmology, St. Louis Medical College.

CHARLES E. HACKLEY, M.D...NEW YORK, N. Y.
Visiting Physician, New York Hospital.

ALLAN McLANE HAMILTON, M.D...NEW YORK, N. Y.
Visiting Physician, Department of Nervous Diseases, Hospital for the Relief of the Ruptured and Crippled.

ROBERT P. HARRIS, M.D......PHILADELPHIA, PA.
Member of the American Philosophical Society and of the Philadelphia Obstetrical Society; Fellow of the College of Physicians of Philadelphia; Corresponding Member, Royal Academy of Surgery of Naples.

S. S. HERRICK, M.D.........SAN FRANCISCO, CAL.

WILLIAM B. HILLS, M.D..........BOSTON, MASS.
Assistant Professor of Chemistry, Harvard Medical School.

W. H. HOWELL, M.D.............BALTIMORE, MD.
Johns Hopkins University.

JAMES NEVINS HYDE, M.D........CHICAGO, ILL.
Professor of Skin and Venereal Diseases, Rush Medical College.

EDWARD JACKSON, M.D......PHILADELPHIA, PA.
Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine.

LAURENCE JOHNSON, M.D.....NEW YORK, N. Y.
Professor of Medical Botany, Medical Department of the University of the City of New York.

HENRY LEFFMANN, M.D.....PHILADELPHIA, PA.
Professor of Clinical Chemistry and Hygiene, Philadelphia Polyclinic; Assistant to the Chair of Chemistry, Jefferson Medical College.

ROBERT W. LOVETT, M.D........BOSTON, MASS.
Assistant in Surgical Out-Patient Department, Boston Children's Hospital; Late House Surgeon, Boston City Hospital.

F. A. MANNING, M.D.........NEW YORK, N. Y.
Late House Surgeon, New York Hospital.

MIDDLETON MICHEL, M.D.....CHARLESTON, S. C.
Professor of Physiology, Medical College of the State of South Carolina; Visiting Surgeon, City Hospital, Charleston.

CHARLES SEDGWICK MINOT, M.D..BOSTON, MASS.
Assistant Professor of Histology and Embryology, Harvard Medical School.

ROBERT B. MORISON, M.D.......BALTIMORE, MD.
Professor of Dermatology and Syphilis, Baltimore Polyclinic and Post-Graduate Medical School.

H. H. MUDD, M.D.................ST. LOUIS, MO.
Professor of Anatomy and Clinical Surgery, St. Louis Medical College.

SAMUEL NICKLES, M.D..........CINCINNATI, O.
Professor of Materia Medica, Medical College of Ohio.

WILLIAM OLDRIGHT, M.D.....TORONTO, CANADA.
Lecturer on Sanitary Science, Toronto School of Medicine; Chairman Provincial Board of Health.

FREDERICK N. OWEN, E.M...NEW YORK, N. Y.
Civil and Sanitary Engineer.

ROSWELL PARK, M.D..........BUFFALO, N. Y.
Professor of the Principles and Practice of Surgery, University of Buffalo, N. Y.

THEOPHILUS PARVIN, M.D...PHILADELPHIA, PA.
Professor of Obstetrics and Diseases of Women and Children, Jefferson Medical College.

ABNER POST, M.D. ....BOSTON, MASS.
Surgeon to Out-Patients, Boston City Hospital.

WILLIAM HENRY POTTER, A.B., D.M.D.....BOSTON, MASS.
Demonstrator of Operative Dentistry, Harvard Dental School.

T. MITCHELL PRUDDEN, M.D..NEW YORK, N. Y.
Lecturer on Normal Histology, Yale College; Director of the Physiological and Pathological Laboratory of the Alumni Association, College of Physicians and Surgeons, New York.

LEOPOLD PUTZEL, M.D........NEW YORK, N. Y.
Visiting Physician, Randall's Island Hospital.

HUNTINGTON RICHARDS, M.D......NEW YORK, N. Y.
Aural Surgeon, New York Eye and Ear Infirmary; Chief of Clinic, Department of the Ear, College of Physicians and Surgeons, New York.

THOMAS G. RODDICK, M.D..MONTREAL, CANADA.
Professor of Clinical Surgery, McGill University; Visiting Surgeon, Montreal General Hospital.

J. WEST ROOSEVELT, M.D.....NEW YORK, N. Y.
Professor of the Principles and Practice of Medicine, in the Medical College of the Woman's Infirmary, of New York; Visiting Physician to Bellevue and Roosevelt Hospitals.

IRVING C. ROSSE, M.D........WASHINGTON, D. C.

EDWARD W. SCHAUFFLER, M.D...KANSAS CITY, MO.
Professor of the Principles and Practice of Medicine, Kansas City Medical College.

WILLIAM T. SEDGWICK, PH.D.....BOSTON, MASS.
Assistant Professor of Biology, Massachusetts Institute of Technology.

N. SENN, M.D....................MILWAUKEE, WIS.
Attending Surgeon, Milwaukee Hospital; Professor of the Principles and Practice of Surgery and of Clinical Surgery in the College of Physicians and Surgeons, Chicago, Ill.

CHARLES SMART, M.D. ....WASHINGTON, D. C.
Surgeon, United States Army.

STEPHEN SMITH, M.D ....NEW YORK, N. Y.
Professor of Clinical Surgery, Medical Department of the University of the City of New York; Visiting Surgeon, Bellevue and St. Vincent's Hospitals.

M. ALLEN STARR, M.D., Ph.D..New York, N. Y.
Clinical Lecturer upon Diseases of the Mind and Nervous System, College of Physicians and Surgeons, New York; Attending Physician, Nervous Class, Demilt Dispensary.

THOMAS L. STEDMAN, M.D.....New York, N. Y.
Late Attending Surgeon, New York Orthopædic Dispensary and Hospital.

JAMES STEWART, M.D.......Montreal, Canada.
Professor of Materia Medica and Therapeutics, McGill University.

THOMAS D. SWIFT, M.D........New York, N. Y.
Visiting Physician, Demilt Dispensary.

SAMUEL THEOBALD, M.D........Baltimore, Md.
Attending Surgeon, Baltimore Eye, Ear, and Throat Charity Hospital; Ophthalmic and Aural Surgeon, Saint Joseph's General Hospital, Baltimore.

HENRY S. UPSON, M.D.............Cleveland, O.

ARTHUR VAN HARLINGEN, M.D.....Philadelphia, Pa.
Professor of Diseases of the Skin, Philadelphia Polyclinic and College for Graduates in Medicine: Consulting Physician, Dispensary for Skin Diseases.

GEORGE L. WALTON, M.D.........Boston, Mass.
Assistant in Out Patient Department for Diseases of the Nervous System, Massachusetts General Hospital.

RUDOLPH A. WITTHAUS, M.D..New York, N. Y.
Professor of Chemistry, Medical Department of the University of New York.

LEROY MILTON YALE, M.D.....New York, N. Y.
Visiting Surgeon, Presbyterian Hospital.

HENRY CRÉCY YARROW, M.D.....Washington, D. C.
A. A. Surgeon, United States Army; Honorary Curator, Department of Reptiles, United States National Museum; Professor of Dermatology, National Medical College, Columbian University.

PHILIP ZENNER, M.D..............Cincinnati, O.
Clinical Lecturer upon Diseases of the Nervous System, Medical College of Ohio.

v

A REFERENCE HANDBOOK

OF THE

MEDICAL SCIENCES.

PRAIRIE ITCH. This is an affection, or rather a group of affections, met with frequently in the northern and western portions of this country, but seldom seen in the Southern States, which has long been, and still is, a subject of much dispute among practitioners in the regions first mentioned, as to its nature, cause, and treatment. The literature of the disease is very meagre, and the views of those who have written concerning the affection are so at variance, that it is impossible to avoid the conclusion that they have seen and described different disorders, which have no other relation to each other than that they are all characterized by the one symptom of itching.

The names by which these different forms of pruritus have been designated, are almost as numerous as the localities in which they have been observed. Among others may be mentioned, prairie digs, Michigan itch, Texas mange, lumberman's itch, swamp itch, Ohio scratches, whore's itch, army itch, winter itch, etc.

A general description of the symptoms observed in the majority of these cases, as gathered from the articles on the subject published in various journals, chiefly of the West, is as follows: The affection begins usually rather suddenly, and is not preceded by any premonitory symptoms. The patient is, apparently without any cause, attacked by an intense pruritus, confined usually to the parts covered by the clothing. The itching is worse at night after the sufferer has retired, though he is not entirely free during the day. The sensations are described as itching, burning, or tingling. There is said to be, at times, a papular eruption, followed by the appearance of vesicles, pustules, and sometimes urticarial wheals. After a time the evidences of scratching become visible, and most writers, indeed, regard all the lesions as the direct result of this form of irritation, believing that the affection is a pure pruritus, unaccompanied by any primary lesions. Sometimes there are evidences of considerable dermatitis, the integument surrounding the lesions being of a bright scarlet hue, while a feeling of tension in the skin is complained of. The disease is said by some to be contagious, and many instances have been reported in which it seems difficult to exclude or explain away this element. On the other hand, others assert with equal confidence that no evidences of contagion are present, but that the pruritus occurs frequently in members of one family or community, simply because all are exposed to the same climatic conditions. It is said by some to occur only in those regions where the inhabitants are exposed to sudden and extensive variations of temperature. Others assert that it is as troublesome in milder climates and during the warmer seasons of the year, as it is in winter and in places where the temperature of the atmosphere is subject to great changes.

The affection is, by some, regarded as an eczema papulosum; others believe that the great majority of the cases are nothing more than pruritus hiemalis; some, again, look upon it as scabies pure and simple, while still others incline to the opinion that it is a disease *sui generis*, and due to the presence of a micro-organism in the layers of the skin. It is very probable that all of these different observers are right, and that there are several diseases grouped under the one name of prairie itch. Dr. J. N. Hyde, of Chicago, who has made a very careful study of pruritus hiemalis, believes that most cases of prairie itch are instances of the first-named disease, though he thinks that some cases of scabies, and possibly of other forms of disease, are included by various observers under this common designation. Dr. J. E. Engsted, of Dakota, has described a parasite which he has found in cases of prairie itch. The organisms appear as flattened cells, of varying lengths, arranged usually in chains of from five to twenty links, or as oval cells with from four to twenty hooklets projecting from their sides.

The treatment which has been recommended for prairie itch naturally varies according to the views that different observers hold concerning the nature and cause of the disease. Those who believe that the affection is contagious and due to the presence of a parasite, whether animal or vegetable, advise the employment of one or other of the various parasiticides, such as mercurial or sulphur ointments, naphthol, carbolic acid, hyposulphite of soda, etc. The secret of success, they say, is in the persistent and thorough application of these remedies; internal medication is without avail. Others, who reject the parasitic theory, also advise external applications, but of antipruritic rather than of antiparasitic remedies. Alkaline lotions, bismuth or starch powders, various preparations of carbolic acid, one part each of chloral and camphor in eight parts of unguentum aquæ rosæ, lead lotions, diachylon ointment, etc., are among the remedies of this sort which have been found more or less efficacious in different cases. Hyde insists upon regulation of the diet, and the avoidance of all articles of food or medicaments which are capable of exciting cutaneous rashes or of aggravating pruritic symptoms. Of course, strict cleanliness and the avoidance of underclothing made of rough and irritating material are very essential points in the treatment, whatever the cause or the nature of the pruritus may be.

During the fall of 1886, many short communications on prairie itch appeared in the medical journals of this country. The reader may find information of value in the issues at that time of the Detroit *Medical Age*, the *Journal of Cutaneous and Venereal Diseases*, the New York *Medical Record*, and other journals, chiefly those of the West.

Much assistance in the preparation of this brief sketch has been derived from the several articles in these journals, and also from a pamphlet on "The Affections of the Skin Induced by Temperature Variations in Cold Weather," by Dr. James Nevins Hyde, of Chicago.

T. L. S.

PREGNANCY. Pregnancy is the condition of a woman who has within her the product of conception. It begins with fecundation, and ends with the expulsion or removal of the fecundated ovule, no matter how far

the process of development has been carried, nor how long after development has ceased the ovum has been retained.

The word pregnancy, going back to its Latin etymology in the verb *gigno*, thence to the Greek *γενναω*, and finally to the Sanscrit *zan*, or *gan*, carries with it as the essential idea reproduction. But, on the other hand, the usual synonyms merely express one or another phenomenon of the pregnant condition. Thus, the English gestation, from the Latin *gestatio*, the German *Schwangerschaft*, and the Greek *κυεσις*, are each derived from a verb signifying in these different languages to carry; the Latin *graviditas*, and the Italian *gravidanza*, indicate the increased weight caused by pregnancy, and the French *grossesse* the greater size.

In normal pregnancy, the only variety which will be considered in this article, the fecundated ovule is developed in the cavity of the uterus—that is, the pregnancy is uterine, not extra-uterine. The pregnancy is simple, or single, when only one ovum occupies the uterus; but if two or more, it is called multiple, or pluriparous.

Duration of Pregnancy.—As has been indicated, a woman becomes pregnant when conception occurs, that is, if there is an actual union between the ovule and the spermatozoid, but when this occurs is one of nature's secrets which probably she will never reveal, and hence the actual beginning of pregnancy we cannot tell. Pregnancy, an internal incubation corresponding with the external which occurs in fowls, continues until the fœtus is best prepared to live external to the mother, and is usually regarded as lasting from about two hundred and seventy to two hundred and eighty days, or in other words, nine solar or ten lunar months. It is true that a fœtus born some weeks earlier than the shorter period stated may live, and therefore is said to be viable, though the chances of living lessen as the normal period of pregnancy is receded from. Obstetricians have, until recently, fixed upon seven months of intra-uterine life as the period when viability begins. But occasional exceptions have been observed, that is, children born at between six and seven months live; and as recently, by means of the *couveuse* and *gavage*, the number of exceptions is increasing, Tarnier suggests that this period should be six months, thus corresponding with the civil law of France, which makes a child legitimate if born at the expiration of one hundred and eighty days after the time when impregnation by the husband was possible.

Changes caused by Pregnancy.—Two important series of changes result from pregnancy—the one belonging to the impregnated ovule, and the other to the maternal organism. The former changes have been presented elsewhere in this work, and therefore there will be considered in this article only those concerning the mother.

The maternal alterations consequent upon pregnancy are conveniently divided into local and general. The former belong chiefly to the sexual organs, and will be first presented.

Changes in the Sexual Organs.—These organs in the female include those of reproduction, and those of lactation, and the alterations in each are to be considered in tracing the history of pregnancy. The most remarkable modifications occur in the organ of gestation, the uterus. It is the home for nine months of the new being, which in its rapid and marvellous development requires ample supply of nutritive material and constantly increasing room. But the uterus, in the earlier months or weeks of pregnancy, increases in size and capacity quite independently of any mechanical action of the ovum, for the latter is at first too small to produce such effects; and also, the changes just mentioned are observed when the uterus is quite empty, that is, when the pregnancy is extra-uterine.

The first modifications occur in the mucous membrane, which undergoes hypertrophy and hyperplasia, and furnishes the external covering of the ovum, the deciduous membrane. This deciduous membrane admits of a threefold division. First, that upon which the ovule rests, and which contributes to the formation of the placenta; this has been known from the time of John Hunter as the *decidua serotina*, because it was believed to be formed after the other deciduæ; second, that arising from the hypertrophied folds of this tissue between which the ovule is placed, and which uniting over it, make a complete covering, and which was called the *decidua reflexa*, because it was thought that the impregnated ovule entering the uterus, pushed away an exudate which was supposed to be formed as a consequence of impregnation, and which completely lined its cavity; and third, the decidua which occupies the rest of the internal surface of the uterus, but which in the latter part of the third, or early in the fourth, month of pregnancy unites with the decidua immediately covering the ovule, and is known as the *decidua vera*.

The peritoneal investment of the uterus undergoes remarkable increase, for without being thinned it still covers the organ enormously increased in size at the end of pregnancy.

The muscular tissue of the organ is greatly developed. Not only is there hypertrophy of already existing muscular fibres—these fibres becoming ten times longer and five times broader—but there is an actual hyperplasia, new contractile tissue being formed. Blood-vessels and nerves also increase in size; the veins indeed, in certain parts of the uterine wall, become so enlarged that they are called sinuses; hypertrophy of the lymphatics is well marked. The increased size of the uterus may, toward the end of pregnancy, result in part from passive stretching of the tissues composing its walls; but early in the pregnant state these walls are thicker than in the unimpregnated condition, and while the neck becomes greatly stretched and thinned, the fundus at the end of pregnancy remains thick; indeed, the entire wall of the body of the uterus may undergo even then no thinning in some cases. The weight of the uterus at the end of pregnancy is thirty-three times that of the nulliparous organ, eighteen times that of the parous. At this time its length is twelve inches and three-fourths, its breadth nine inches and a half, and its antero-posterior measurement nine inches. According to the late Sir James Simpson, the surface of the unimpregnated uterus is five or six square inches, and its capacity one cubic inch; but at the end of the pregnancy the former is three hundred and fifty square inches, and the latter four hundred cubic inches.

Changes in the form and the position of the uterus result from pregnancy. In the virgin the organ is at first pear-shaped, but flattened antero-posteriorly; the body of the uterus next becomes somewhat spheroidal in form, and finally the ovoidal shape is well marked, especially as the cavity of the neck contributes to the general uterine cavity, or in other words, effacement of the neck takes place; the larger end of the ovoid is above. At first the impregnated uterus sinks somewhat in the true pelvis, though this generally received statement is disputed by Tarnier; in the course of the fourth month, however, the increase in size of the organ is so great that there is not sufficient room in the pelvic cavity, and hence the uterus ascends; the process of ascension continues until, at the middle of the ninth month, the fundus reaches as high as the lower portion of the ensiform cartilage; and then, more especially if the subject be a primigravida, descent occurs, the presenting part of the fœtus, still, of course, enclosed in the uterus, enters the pelvic cavity, and the upper part of the womb, while lower than it was, projects more in front, causing a notable change in the form of the abdomen. In a multigravida the ascension is never so great, because the relaxed abdominal walls do not compel so decided a change, nor does the descent toward the end of pregnancy occur so soon—indeed it may not be manifested until labor actually begins. Of course, in case of a mal-presentation, this phenomenon fails. The gravid uterus is seldom found in the median line, but is usually inclined toward one or the other, in the great majority of cases the right, side. So, too, in the development of the uterus there is a torsion of the organ, a movement upon its longitudinal axis

by which the left side is thrown more anteriorly, while, of course, the right recedes; this fact is of importance when auscultating for the purpose of hearing the uterine souffle, for this sound, being most distinct at the sides of the uterus, will be best heard at that side to which the stethoscope can be most readily applied. Uterine torsion is readily explained by reference to the embryological development of the organ. Lateroversion of the uterus, the inclination being usually, as has been stated, toward the right side, should be remembered in performing the Cæsarean section, for after opening the abdominal cavity it is important, in order that incision of the uterus shall be made in the median line, to press the organ from the side to which it is inclined so that it will occupy a central position.

Changes in the properties of the uterus are to be considered. While the walls of the unimpregnated uterus are firm and resisting, with the progress of pregnancy they become yielding and elastic, thus permitting momentary changes in form resulting from fœtal movements, or from changes of position or other movements of the woman herself, or from external pressure. Following these various modifications in shape, as for example, those caused by fœtal movements, the uterus recovers its normal form, partly as a consequence of its elasticity, and in part from its retractility.

The sensibility of the uterus is only apparently, not really, increased; the size of the organ being so much greater, the latter is more exposed, and then, too, it is liable to certain pathological conditions which are characterized by more or less suffering referred to it. The irritability of the uterus is greater in pregnancy; the organ responds more readily to causes which excite the action of its muscular fibres, and in some subjects this reflex excitability is so decided that miscarriage is liable to result from comparatively trivial causes. But, on the other hand, this irritability in others is so slight that the greatest violences may be inflicted upon the subject without the pregnancy being interrupted. In consequence of the vast increase in the muscular tissue of the uterus, its contractile power is greatly augmented. This power is manifested first by what are known as the painless contractions of pregnancy, these contractions beginning as early as the fifth month, occurring at irregular intervals, and observed throughout the succeeding portion of pregnancy, and finally and chiefly by the contractions of labor, these contractions causing more or less suffering. The painless contractions of pregnancy are of importance in promoting the uterine venous circulation; they possibly contribute in slight degree in maintaining the attitude of the fœtus, as they are a factor in causing its position.

In addition to the changes already described, and which relate chiefly or exclusively to the body of the uterus, those occurring in the neck are to be mentioned. The neck of the womb undergoes only slight hypertrophy in pregnancy; it is less abundantly supplied with blood than the body is, and is not subjected to a stimulus from the growing ovum. The position of the neck depends upon the position of the body; thus, if the latter be inclined to the right side and anteriorly, the former will point to the left and backward. It should be remembered, however, especially if the subject be a multigravida, and the abdominal wall be greatly relaxed, there is in most cases more or less uterine anteflexion; this comparatively frequent condition should be borne in mind in those instances in which a bougie is introduced into the uterus for the purpose of bringing on premature labor, or the same object sought by introducing dilators into the cervical canal; for harm may result, or simply difficulty, from the effort to force any of these bodies in that which is the usual direction of the canal in the non-pregnant. Apparent shortening of the neck results from the ascension of the body of the uterus in the abdominal cavity, but actual shortening, it is generally held, does not occur in the majority of cases until the latter part of pregnancy—in many instances, indeed, not until just before the beginning of labor.

Early in pregnancy a change in consistence of that part of the intravaginal cervix immediately adjacent to the external os occurs, the superficial tissues becoming softer. This softening advances regularly and slowly in the primigravida, until it involves the entire vaginal portion, so that, approximately, one-fourth is affected at four months, one-half at six, three-fourths at seven, and the remaining fourth is also softened at eight months. In the multigravida the process is more rapid, because the vaginal portion is shorter, and because it has once or oftener previously undergone the change.

The form of the neck of the womb in the primigravida is at first more distinctly conical, but it soon becomes spindle-shaped from the accumulation of glandular secretions in the cervical canal; in the multigravida it is cylindrical, or somewhat expanded at its lower portion, so that it becomes club-shaped. The external orifice of the uterus in the former remains closed until the end of pregnancy; in only very rare instances it may be more or less permeable by the finger in the latter weeks of pregnancy. In multigravidæ the external os is not surrounded by a uniformly smooth surface, but the border is irregular and fissured, the most distinct of the fissures being found in the majority of cases upon the left side; the cervical canal is permeable by the finger to a distance directly related to the duration of the pregnancy, the finger readily passing to the middle of it at seven months; the cavity which the canal presents is funnel-shaped, or we may regard the neck of the womb as a hollow cone with its base below. The vagina is elongated by the ascension of the uterus; it is swollen, moister, its papillæ more distinct, and acquires a peculiar violet or purplish hue, arising from the increase of venous blood—this being one of the signs of pregnancy first pointed out by Jacquemin, and the value of which has recently been urged by Chadwick; greater arterial supply gives origin to the vaginal pulse, a sign of pregnancy which was pointed out by Osiander. The external genital organs are swollen, and have an increased secretion; the inner surfaces of the vulva may show a similar, though less marked, change of color to that observed in the walls of the vagina; varicose veins are found in some cases.

The ovaries, in consequence of changes in the broad ligaments, ascend in the abdominal cavity, come nearer the uterus, and have an almost vertical direction; they increase, according to Jacquemier, to about twice their usual size; ovulation, as a rule, is suspended, but the last *corpus luteum* undergoes remarkable hypertrophy, and disappears much later than that which follows menstruation without impregnation; indeed, it has been found well marked in women dying during the lying-in period. The broad ligaments open up their peritoneal folds to receive between them the enlarged uterus, and become almost vertical; they increase in length and thickness. The round ligaments become greatly hypertrophied, so that they can be readily felt in thin subjects then, and also during labor. In consequence of the greater increase of the posterior than of the anterior wall of the uterus, their uterine insertion, instead of being median as to the sides of the uterus, is now at the junction of the posterior four-fifths with the anterior fifth of the lateral face of the uterus; their hypertrophy and change of position prepare them for their office during labor, drawing the superior part of the uterus forward and downward, thus causing the uterine axis to be brought in correspondence, during a "pain," with the axis of the pelvic inlet. The development of the round ligaments in pregnancy, one of them being usually larger than the other, may furnish a probable prognosis as to the vigor of uterine contractions, for the greater that development, the greater likewise is that of the uterine muscular tissue.

The oviducts participate in the general hypertrophy, and, like the ovaries, occupy a vertical position.

The changes in the mammary glands are very important and characteristic. In some instances the breasts become larger at the beginning of pregnancy, but in the majority of cases no increase in size occurs until at the time of the first menstrual suppression; according to Zweifel, this enlargement probably depends upon accumulation of fat between the lobules. The breasts may

be the seat of occasional shooting pains, and there may be increased sensibility of the axillary glands. The superficial veins are larger and more distinct, their blue color strikingly contrasting with the whiteness of the skin; if the breasts are greatly enlarged, it is not unusual to observe striæ upon them similar to those found upon the abdominal wall. The latter part of the second, or in the third, month the nipple is found more prominent and sensitive, firmer and harder; then, too, possibly a milk-like fluid may spontaneously escape or be pressed from it, though this phenomenon does not usually occur until in the last three months, and, on the other hand, in some instances, has been observed independently of pregnancy. The changes in the areola surrounding the nipple are very characteristic. First an apparently emphysematous swelling is observed, then an alteration in color corresponding to that of the hair and of the skin, and hence in blondes simply a deep rose color, and in brunettes a brown which grows darker with the progress of pregnancy: change in color is least in those having red

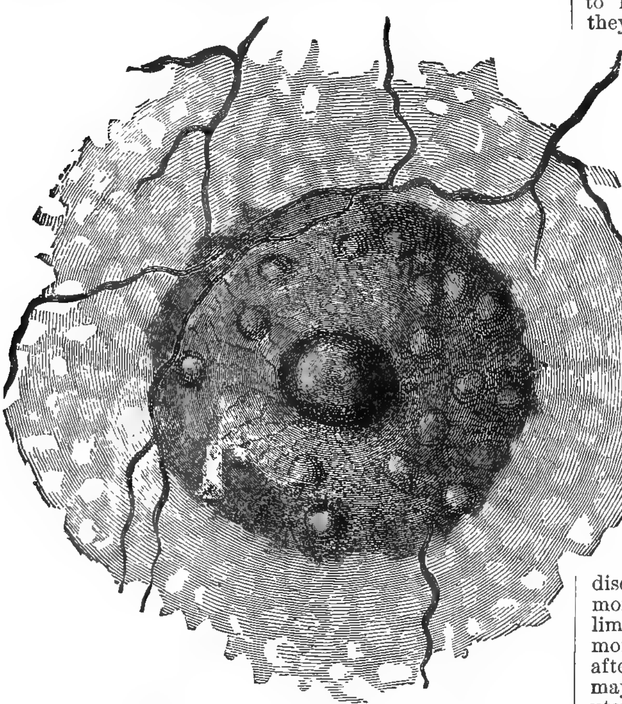

FIG. 3083.—Changes in the Breast caused by Pregnancy.

hair, and in them may even be not apparent. Montgomery's glands, the *glandulæ lactiferæ aberrantes* of Henle, notably increase in size, projecting from the sixteenth to the eighteenth of an inch. In addition to the primary areola, which has a radius of about one inch, a secondary areola surrounding it appears in the fifth or in the sixth month; this is lighter in color and flecked with whitish spots, presenting an appearance similar to a piece of dusty-white blotting-paper upon which drops of water have fallen. The illustration given above shows very well the changes that have been described in the nipple, the development of the glands of Montgomery, the appearance of the primary areola, and the formation of the secondary areola.

Disorders of urination are commonly observed during pregnancy. In the early weeks, in consequence of the pressure and sinking of the uterus, there usually is vesical irritability, while in the last weeks the descent of the presenting part of the fœtus into the pelvic cavity may, by pressure upon the urethra, cause ischuria. Pressure upon the rectum may produce constipation, though this is in many cases quite as frequently the result of the more sedentary habits of the woman when pregnant; partly as the consequence of the hyperæmia of the pelvic viscera generally, and partly from interruption by the enlarged uterus to venous return, hæmorrhoids are not uncommon in the pregnant woman.

The chief changes in the abdominal wall, in addition to its great stretching, are pigmentation over the *linea alba*, so that there is found a *linea nigra*, the formation of striæ, and the alterations in form of the umbilicus. The pigmentation referred to extends from the pubes to the navel, and, in some cases, above the latter, the discoloration then either forming a semicircle upon one side, or completely encircling it, before passing up toward the ensiform cartilage; the distinctness and the depth of the color are in relation to the color of the subject, and hence much more pronounced in the brunette. Abdominal striæ, the so-called cicatrices of pregnancy, occupy each side of the abdominal wall below the umbilicus, and are arranged in a series; they are in almost all cases present in first pregnancies, and it is not uncommon to find new ones in the multigravidæ. When recent they are a deep rose color, sometimes they are purplish, but after labor they become white or pearl-colored; generally the surface is depressed, but in some cases, as the result of serous effusion from compression of the epigastric vein, it is prominent. These striæ are the consequences of partial or complete atrophy of the lymph-spaces, partial atrophy of the skin, and longitudinal arrangement of the fibres of connective tissue. They may be absent in women who have borne many children, and they may be present in women who have never been pregnant; such instances, however, are exceptional.

During the first three months of pregnancy the umbilical depression is slightly increased, or remains unchanged; in the fifth month it is found notably lessened, and at seven months has disappeared; in the last two months there is more or less protrusion.

General Changes caused by Pregnancy.—Among the most important and earliest of the changes in the organism are those affecting the digestive organs. Gastric disturbance occurs in the first months of pregnancy in almost all cases. In some it may be so slight as scarcely to be an indisposition, only a transient discomfort; but in others so severe as to be a grave disease. From the fact that the nausea and vomiting are more frequent in the early part of the day—in some cases limited to this time—the condition is commonly called morning-sickness. Generally this disorder disappears after the first four months, but later in pregnancy there may be gastric irritability, caused by pressure of the uterus upon the stomach.

Both quantitative and qualitative changes in the blood occur in pregnancy. That there is an actual increase in the quantity of blood is proved by the larger area of the circulation and by the fulness of the vessels, a fulness which may contribute to the development of varicose veins, or to serous effusion. There is an increase in the watery portion of the blood and of the white cells, but a decrease in the albumen, the red corpuscles, and iron; the fibrin, normally 3 parts to 1,000, lessens until the sixth month, when it begins to become greater, and at the end of pregnancy is 4.3. Increased work is thrown upon the heart to send a larger quantity of blood through a larger area, and a consequent hypertrophy, involving especially the left ventricle, occurs.* The ascent of the

* Larcher, in 1857, first made known the fact of cardiac hypertrophy in pregnancy. He stated that this hypertrophy occurred chiefly in the left ventricle, its walls becoming one-fourth thicker at least, one-third at most. Ducrest confirmed the investigations of Larcher, and Blot further proved that the heart increased more than one-fifth in weight. Löhlein, among others, on the other hand, maintained that the cardiac hypertrophy of pregnancy does not exist. Zweifel states that the thorough investigations of Müller, of Jena, led him to conclude that this hypertrophy does occur, though not to the extent asserted by Larcher and others; and that the cardiac increase corresponds to the general increase of the body, for in every such increase the heart's muscular mass has a proportional increment.

diaphragm lessens the pulmonary capacity, so too the antero-posterior measurement of the chest decreases ; but there is a compensating increase in the transverse measurement; nevertheless, it seems doubtful if there be complete compensation, for the pregnant woman, when the uterus interferes most with the descent of the diaphragm, is liable to suffer from hurried breathing, as in rapid walking or in ascending steps. Resulting from the greater quantity of the blood and the greater arterial tension, the quantity of urine secreted increases ; this increase is almost exclusively of its watery portion ; all the solid constituents, with the exception of the chlorides, progressively lessen with the advance of the pregnancy. Nauche, in 1831, described what was at first thought to be an organic substance found upon the urine of pregnant women about thirty-six hours after it was passed, and which received the name of kyesteine, since it was regarded as characteristic of the pregnant condition ; this is a soft, grumous, white pellicle, which about the fifth day breaks up and falls to the bottom of the vessel. So far from being an organic substance, it is chiefly composed of ammonio-magnesian phosphates, vibrions, and monads ; it may be found upon the urine of the non-pregnant, as well as upon that of the male. It is not uncommon for the urine to be albuminous, especially in the latter part of pregnancy ; but if this be slight, and caused by vesical catarrh, the condition need give no anxiety. Still more rarely, sugar is found in the urine toward the end of pregnancy, and is simply significant of the elimination of milk-sugar ; true diabetes mellitus is rarely seen in pregnant women. According to the observations of Rokitansky, 1838, in more than one-half of pregnant women there are bone-like deposits upon the internal table of the cranial bones, and external to the dura mater, which he called osseous neoplasms or osteophytes. Similar deposits have also been found upon the internal surface of the pelvic bones of women dying in childbed. While these deposits are not exclusively found in connection with pregnancy, for they have also been observed in the tuberculous, yet they are more frequent in the former than in any other condition.

The spleen and also the thyroid gland increase in size ; it is probable, too, that the kidneys become somewhat larger in pregnancy.

Pregnancy causes greater nervous sensibility, and hence various reflex nervous disturbances may occur. Neuralgic affections, especially involving one or more teeth, are not uncommon ; often the severe toothache may require, or be thought to require, extraction of the painful organ, and women who have borne many children will sometimes say that every child has cost them a tooth. Many women are despondent and a prey to gloomy thoughts or grave apprehensions of danger, and in some actual insanity occurs ; but in the majority of instances of mental derangement hereditary influence is the important factor, pregnancy being merely the exciting cause.

A woman's weight increases about one-thirteenth during pregnancy, this increase being greatest in the last three months—being from one kilogram and a half to two kilograms (from 4 to 5½ pounds) each month.

Multiple Pregnancy.—When two or more fecundated ovules occupy the uterus, the pregnancy is called multiple, or pluriparous.

Twin pregnancy occurs once in 90 ; triple, once in 7,900 ; and quadruple, once in 370,000—though Neefe, quoted by Zweifel, makes the latter proportion 1 to 560,000 ; quintuple pregnancy is of course exceedingly rare. The frequency of pluriparous births varies in different countries, and, contrary to the opinion of Pliny, such births are not more frequent in warm climates ; thus they occur oftener in Denmark and Sweden than in France and Belgium.

The sex of the children is the same in sixty-four per cent., different in thirty-six per cent.

Multiparity and heredity seem to be the most important factors in the production of multiple pregnancy ; but in addition to these, other causes apparently are great stature, race, and the size of the ovaries.

In pluriparous inferior animals fecundation of ovules is simultaneous, and probably this is the fact in multiple pregnancy in the human female in the majority of cases ; nevertheless there are a few instances recorded where the fecundation was successive, so that it may be admitted that a woman who has already conceived may, while that product of conception remains, conceive again—in other words super-impregnation may occur. But super-impregnation includes super-fecundation, and super-fœtation. By the former is meant the fructification of ovules liberated about the same time, and by the latter the fructification of ovules escaping at an interval of weeks or even of months, an hypothesis that is generally rejected ; this rejection rests upon physiological and anatomical grounds. First, we have reason to believe that ovulation is suspended during pregnancy. Just as the hen does not lay eggs after she has begun setting, so the human female does not, while the process of internal incubation is going on, furnish any new ovules for impregnation. Then, too, between the third and fourth months the decidua covering the ovum and that lining the uterus are fused into a single membrane, so that ascension of the spermatozoids to the usual seat of impregnation is impossible, and also, entrance of the ovule, impregnated or not, into the uterus is for a like reason impossible. Therefore, while that variety of super-impregnation known as super-fecundation is admitted, the other, super-fœtation, is in the highest degree improbable, and after the fusion of the deciduous membranes, impossible. There is not space in the present article to consider and to answer the facts adduced in favor of the latter hypothesis.

In order that twin conception may occur, there may be, first, two ovules furnished by two ovisacs, both of the latter belonging to one ovary, or one from each ovary ; then there will be two corpora lutea. Second, one ovisac may contain two ovules ; this is not a mere hypothesis, for some observers have found an ovisac with even three ovules. Third, there may be two germinal vesicles in a single ovule, or the blastodermic membrane may divide into two. If the twins come from a single ovule, they are of the same sex.

In the first variety the twins are enclosed in separate sacs, the walls of which are made each of an amnion and of a chorion ; originally each sac had its separate decidual investment, but pressure caused absorption of the intervening decidual walls, so that then a single decidua covers them. The placentæ are completely separate, or united only by a membranous band, but in either case there is no vascular anastomosis. Yet it may also happen that, though the twin conception results from two ovules coming from different ovisacs, there is a common chorion, but separate amnions, and the explanation proposed is that originally each had its own chorion, but, as stated in regard to the two deciduæ becoming one, the intervening double chorion wall has undergone absorption. In these cases the placentæ make a single mass, but ordinarily the vessels do not anastomose. If the twins originate from a single ovule they are enclosed in a common sac, but of course originally each twin had its own amnion ; for that is a production from the embryo, and the fact of there being a common sac has the same explanation as that which has been given for the presence of a common decidua and a common chorion. The placentæ form a single mass, and the blood-vessels anastomose. According to Schatz (*Archiv für Gynäcol.*, Band xxxii.), usually there remains but one anastomosis, and that arterial ; sometimes there is also a venous anastomosis, and rarely two of each.

The weight and size of twins is usually under the average ; very frequently one is larger than the other ; in some cases a twin dies in the course of the pregnancy, while the other reaches complete development ; premature labor is frequently observed in twin pregnancies, still more is it the rule in other varieties of multiple pregnancy.

The diagnosis of pluriparous will be considered in connection with that of single pregnancy.

Diagnosis of Pregnancy.—This is a subject of very great importance with reference to the reputation of the

physician, and hence the honor of medicine, because the two are indissolubly united; but especially with reference to the reputation of the woman, supposing her to be falsely accused, and it may be with reference to her health, and in some cases her life even is at stake. The physician is liable to be deceived by false statements made by the woman herself; in some cases she herself is deceived, but in others she means to mislead, either for the purpose of concealing a true pregnancy, or else with the design of extorting money from the alleged father of her unborn offspring, or to secure an interest in an estate.

In the study of the signs of pregnancy, attention is first given to those of which the woman may inform us, then to those which we obtain by actual examination, the latter being such as we learn by the eye, by the ear, and by the sense of touch. The former are called subjective and the latter objective; probability only is given by subjective, but certainty by objective, signs.

The absence of menstruation, morning-sickness, increase in the size of the breasts, occasional pains in them, and their secretion taking place, the abdomen growing larger, and the sensation of quickening—that is, the mother's consciousness of the first fœtal movements—and the repetition from time to time of these movements, constitute the chief evidences of pregnancy which can be given by the woman herself. But there may be an amenorrhœa independently of pregnancy, or a girl may become pregnant before she has menstruated, or a woman during the temporary and normal absence of the periodic flow, as when she is nursing. On the other hand, there may be, especially in the early months of pregnancy, a bloody discharge from the uterus occurring periodically, which, though not menstruation, but a threatening of miscarriage, may be mistaken for the former. It should also be borne in mind that under the intense desire to be pregnant, or, on the other hand, the great fear of such condition, there may be what, from its etiology, has been appropriately termed psychical amenorrhœa. Nausea and vomiting, simulating the morning-sickness, may result from other causes, such as gastric disease, or reflex disorder. Enlargement of the abdomen may occur from neoplasms, or hypertrophies of normal tissues, or from ascitic disease. Some at least of the changes in the breasts that have been mentioned as occurring in pregnancy, may be the consequences of disease in the pelvis or abdomen, *e.g.*, they may occur in connection with the development of ovarian tumors. So far as the perception of fœtal movements by the subject herself is concerned, a woman may believe she recognizes them and be utterly mistaken, even though she has had the experience of such movements in several pregnancies. It is thus seen that none of these signs are positive proofs of pregnancy; the combination of two or more will make the event very probable, but even should they all be asserted to be present, the physician must not rest his diagnosis upon them, especially as certain signs are available.

In studying the objective signs of pregnancy we may conveniently divide them into those addressed to the sense of sight, of touch, and of hearing.

1. *Inspection.*—This includes observing the carriage, countenance, the breasts, the abdomen, and the vagina. The pregnant uterus, especially in multigravidæ in whom, from the relaxation of the abdominal walls, the enlarged organ falls forward, compels the woman to throw the shoulders farther back to compensate for the increased weight in front, and hence a change in the spinal curve. The face may show pigment deposit upon the forehead and the cheeks, constituting, when great, what has been called the mask of pregnancy. The face may be haggard and anxious, and the fulness of the features lessened, more especially in a pregnant woman who has suffered greatly from nausea and vomiting; but it has not the emaciation, the lines descending from the angles of the mouth, and other manifestations characteristic of the ovarian face. The breasts may be examined with reference to increased size, the presence of milk and of striæ, and the prominence of the nipple; and as to the changes in the areola, its swollen condition, development of Montgomery's glands, and darkened hue; if the fifth month of supposed pregnancy has passed, the secondary areola will be in process of formation. The abdomen may be observed as to increase in size, as to the changes in the umbilicus, the presence of the linea nigra, and of striæ, and in regard to the latter as to whether they are old or recent. The chief object in examining the vagina is to ascertain whether it shows the peculiar coloration to which Jacquemin, and more recently Chadwick, have attached such importance as an evidence of pregnancy. The latter, who has given much study to the subject, makes the following statement in the "Transactions of the American Gynecological Society," vol. xi.: "The color begins as a pale violet in the early months, becomes more bluish as pregnancy advances, until it often assumes finally a dusky, almost black, tint." He further states in reference to the cases examined by him, "that, while in the majority of cases the bluish tinge appeared over the whole vaginal entrance, there was a fair proportion in which the violet tint was confined to the anterior wall of the vagina, just below the urinary meatus, whence it shaded off into the normal pink color laterally. This, when distinctly perceptible, I soon found to be, in my practice, an absolutely sure sign of pregnancy. There were, furthermore, a very few in whom the blue tint was universal, but more accentuated on the posterior wall of the vaginal entrance, which I found was valueless as a sign of pregnancy unless the color was quite deep. The recognition of this peculiar localization of the blue tint on the anterior wall as a sure sign of pregnancy, I feel is the most important new point in this communication."

2. *Touch.*—Obstetric touch is usually applied to an examination made with one or more fingers, introduced into the vagina for the purpose of diagnosis. But the term should be given a far wider signification; we touch, whether the entire hand or only a single finger be employed, and so it is an appeal to the same sense, whether the application be made to the abdominal wall or through one of the canals opening from the lower part of the body—chiefly the vagina, more rarely the rectum, and still more rarely the urethra. To the application of the hand or hands to the abdomen the term external examination, or abdominal palpation, is given; internal and external examination may be made at the same time, the one assisting the other, and then the method is sometimes called the combined examination. By abdominal palpation we may recognize the uterus enlarged by pregnancy from its form, from its being the seat of intermittent contractions, from its containing within it a mobile body, the mobility being either spontaneous or communicated; we may distinguish different parts of that body—the feet, the back, the head, and the pelvis. Palpation is usually done with the woman lying upon her back, the head and shoulders slightly elevated, and the lower limbs moderately flexed, so that the abdominal wall is somewhat relaxed; it is important that the bladder and rectum shall have been recently emptied; the abdomen should be exposed as far down as the mons veneris. The examiner, his hands having been carefully washed and warmed, standing with his back toward the woman's face, and supposing him to be on the right side of the bed,* applies the left hand upon the hypogastrium, first gently, then presses with some firmness, this pressure being most marked at the ulnar side and made just as he is about to raise the hand to place it a little higher upon the abdomen. The ascending movement is made, similar pressure follows, and thus the manipulation is continued until the ulnar side suddenly meets with a marked lessening of resistance, so that it sinks, readily depressing the abdominal wall at that point, and the hand circumscribes the fundus.

Another method of beginning palpation, and by which the lateral boundaries of the uterus are first defined, is to

* By some it is advised to begin abdominal palpation by pressure with two hands upon various parts of the abdomen, so as to accustom it to such contact, and prevent contractions of its muscles; but this preliminary manipulation may be omitted in most cases, and direct exploration at once made.

place the palms of the hands in contact directly in the median line upon the lower part of the abdomen, as represented in the subjoined cut (Fig. 3085). Then the hands are gradually separated, the ulnar margin pressing downward upon the abdominal wall, until, having reached the sides of the uterus, they readily sink, and include be-

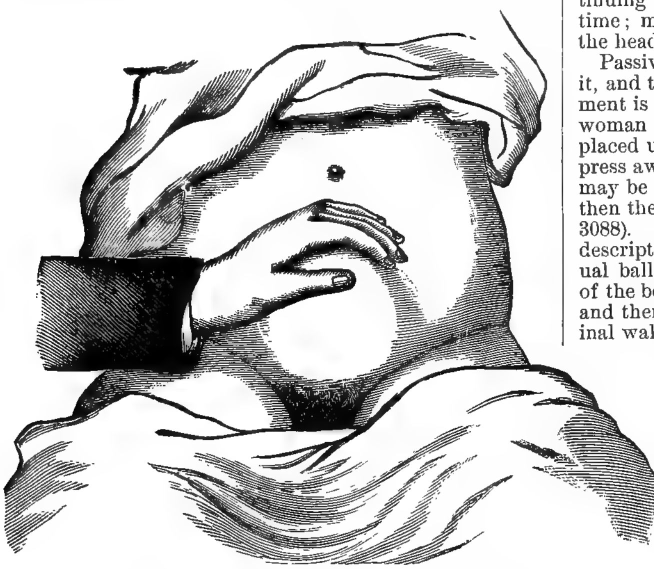

FIG. 3084.—Circumscribing the Fundus of the Uterus.

tween them this organ. It is not then difficult to have them pass farther and farther upward upon the side of the uterus, until the fundus is reached and can be circumscribed.

Dr. Braxton Hicks claims that if the uterus be examined without friction, or any pressure beyond that necessary for full contact of the hand, continuously over a period of from five to twenty minutes, it will be noticed to become firm if relaxed at first, and more or less flaccid

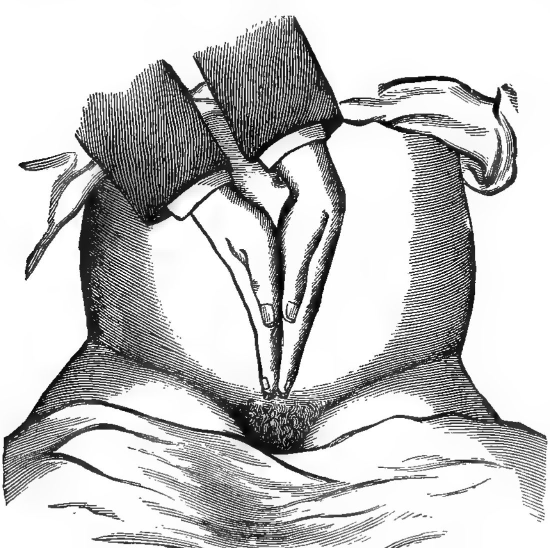

FIG. 3085.—Application of the Hands in the Median Line.

if it be firm at first; each contraction lasts from two to five minutes, and they are seldom separated by so long an interval as thirty minutes: he has found this sign as early as the last of the third month.

At five months the walls of the uterus have become so elastic and depressible, and the fœtus is so developed, that it can be recognized by palpation if the abdominal walls are not too thick. In this examination some parts of the uterine tumor readily yield, while others are resistant, and the latter may in some cases be recognized by continuing the manipulation on one part of the fœtus at a time; most probably in the lower part of the abdomen the head may be felt.

Passive movements may be given the fœtus, or part of it, and to such movements the term abdominal ballottement is given. Usually, in performing ballottement the woman lies upon her back, and the operator's hands are placed upon each side of the uterus; one hand is used to press away the fœtus toward the opposite side, or motion may be given to a part of the fœtus, as the head, and then the manœuvre is called cephalic ballottement (Fig. 3088). The late Dr. Albert H. Smith gave the following description of his method of performing external bimanual ballottement: The woman is placed upon the edge of the bed with her clothing removed from the abdomen, and then rolled upon her side so that the anterior abdominal wall projects over the edge of the bed; then the rotation of her body is carried still farther, until the enlarged uterus becomes so dependent that it may be supported by the hand placed beneath it, while the other hand makes counter-pressure upon the opposite side of the uterine mass. Thus let the woman be upon her left side, the right side, therefore, being above; the examiner takes his seat with his face toward her head, his left side being toward the pendent abdominal mass, but about opposite the hips. The right hand is then passed far under the uterus as it projects over the bed, the palmar surface being in contact with the abdominal integument and the ulnar edge toward the iliac bone. The left hand is then placed similarly upon the right side of the abdomen, making counter-pressure upon the opposite side of the uterine body so as to grasp it between the two palms. This gives a full command of the tumor, and enables the examiner to apprehend the shape and density of the mass, its fluctuating character, the movement of a separate body in it, which can be operated upon by manipulation and repercussion.

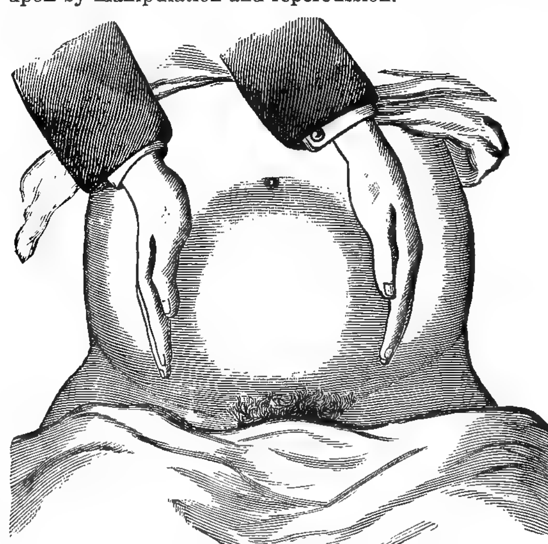

FIG. 3086.—Application of the Hands to the Sides of the Uterus.

Spontaneous movements of the fœtus, which can be readily recognized, are almost certain to occur during abdominal palpation, if the pregnancy has advanced to five months; these movements may be of the entire body or of a member, and in the latter case they are short,

quick taps, for the moment causing a projection at that part of the uterine wall against which the blow is given, and hence may be seen as well as felt; if the entire body

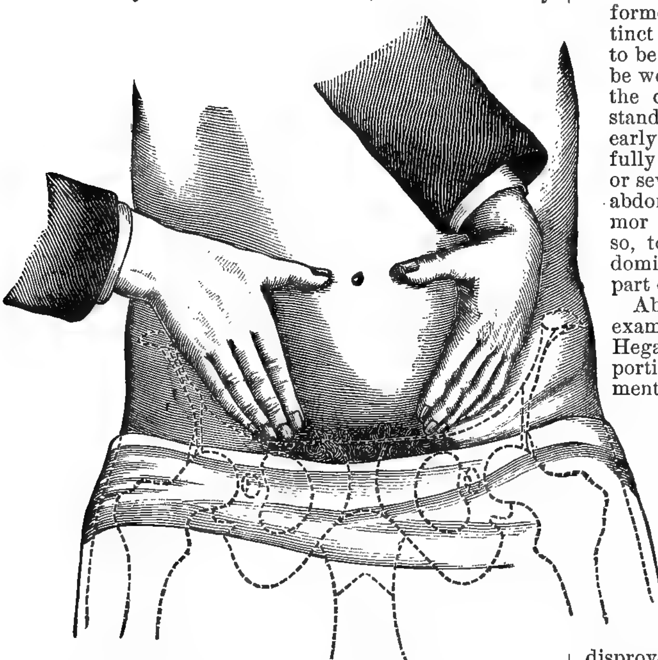

FIG. 3087—The Fœtal Head included between the Examiner's Hands.

moves the motion is slow and gliding, and there is no sudden localized change in the form of the uterus.

By palpation it is possible in most cases, when the pregnancy has advanced to seven months, to recognize different parts of the fœtus, as, for example, the head and the breech with the intermediate back, and also parts of the lower limbs.

By the vaginal examination we chiefly seek to learn the form, position, size, and consistence of the vaginal neck, and condition of the external os and cervical canal. It is in almost all cases made with the woman lying upon her back and the lower limbs moderately flexed. The index-finger of the right or of the left hand is generally employed; by using the medius also a gain of a little more than a third of an inch is secured, but the introduction of two fingers may in some cases be very painful, and a single finger has a greater facility of movement, and also more clearly defined sensation. Softening and some enlargement of the neck of the uterus will be ascertained in case the woman be pregnant, and supposing an antero-lateral inclination of the body of the uterus, the neck is found pointing in an opposite direction. The os in the primigravida is round, instead of being a transverse depression; but in almost all cases the tip of the finger cannot enter it, or if it does, is arrested soon after entrance. On the other hand, the os in the multigravida presents an irregular border, marked by fissures and intervening prominences, the fissures being most distinct upon the sides, and the cervical canal is open to a degree in direct relation with the period of pregnancy—the finger, for example, readily passing to the middle of the canal at seven months; the cavity thus entered is funnel-shaped.

Vaginal ballottement is performed with the subject lying, or standing. If in the former position, it is well to press upon the hypogastrium with the free hand, so as to force the lower portion nearer the index-finger of the other hand; or in this case the index and medius may be introduced into the vagina, placed either in front of the cervix or behind it, the latter position being usually preferred; the finger or fingers are made to press firmly against the uterus and upon the fœtal part resting on the latter, and quick pushing upward is made, the movement being thus communicated to the fœtal part, which is for the moment displaced, but afterward returns to its former position; the movement of return is less distinct than that of displacement, and possibly may fail to be recognized. If the woman's shoulders and head be well elevated, the finger may be placed in front of the cervix, the position also selected should she be standing. The latter part of the fifth month is as early as vaginal ballottement can, as a rule, be successfully made, but this sign becomes most distinct at six or seven months. By combining vaginal touch with abdominal palpation the continuity of a doubtful tumor felt in the abdomen with the cervix is proved; so, too, this pressure upon the uterus through the abdominal wall facilitates vaginal examination of the part of the organ accessible to the finger or fingers.

Abdominal pressure is also combined with digital examination through the rectum for the recognition of Hegar's sign, an early softening and relaxation of that portion of the uterus immediately above the attachment of the utero-sacral ligaments, or the posterior portion of the lower uterine segment.

3. *Obstetric Auscultation.*—This is a discovery of the present century. In 1818, Mayor, of Geneva, examining the abdomen of a pregnant woman, first heard the sounds of the fœtal heart, and three years later Kergaradec, of Lausanne, ignorant of the prior success of Mayor, made the same discovery. In addition to this sound Kergaradec also heard a bruit to which, having an erroneous hypothesis of its cause, he gave the name of placental souffle, a name which some writers still use, in spite of the error long ago disproved, instead of calling it the uterine souffle. In addition to these sounds, others may be heard, such as the funic souffle, and those caused by the movements of the fœtus; but the first two are the most important, and they only will be here considered.

The room in which auscultation is made should be

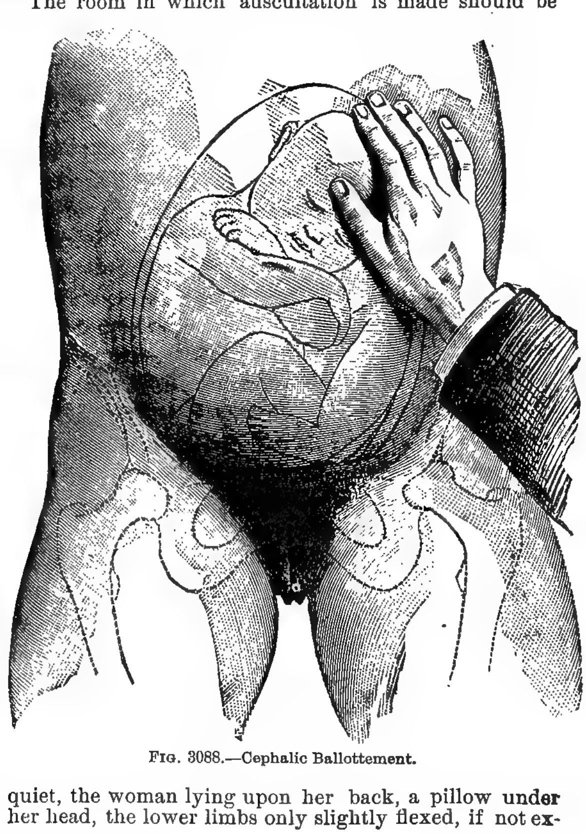

FIG. 3088.—Cephalic Ballottement.

quiet, the woman lying upon her back, a pillow under her head, the lower limbs only slightly flexed, if not ex-

tended, the abdomen naked—though a thin, unstarched muslin or linen covering will in most cases not interfere materially with the examination ; as a rule, a stethoscope should be employed, not only from motives of delicacy, but also for the more certain limitation of the part where certain sounds are heard, and because the ear cannot be readily applied to certain portions of the abdomen where it may be necessary to listen ; nevertheless, the pressure of a stethoscope may in some cases be painful, while the direct application of the ear is readily tolerated, or, again, some may be able to hear more readily without than with an instrument. This examination may be made as early as the last of the fourth month, but for the majority of practitioners, probably, the proofs thence derived of pregnancy will not be distinctly obtained until some time in the fifth month.

The part to which the stethoscope should be applied will be determined by the period of pregnancy, and by whether the sounds of the fœtal heart or the uterine souffle is sought. Should he seek the former, the pregnancy being only four or five months advanced, he will generally best succeed by placing the instrument, in or near the median line, upon the fundus of the uterus, and in a position approximating the axis of the pelvic inlet ; but if the examination be made in the last three months, the uterus having now its ovoidal form, and the long axis of the fœtus corresponding with that of the organ which it occupies, then he should listen at one of the four points, in order, D, C, A, and B (see Fig. 3089).

Obviously, the fœtal heart-sounds will be heard most distinctly through the back of the fœtus, for the dorsal plane of the fœtus by its convexity is better adapted to the concavity of the internal uterine wall, and besides, with the superior members folded over the anterior chest, the heart is consequently made more remote; and, finally, the lungs being not expanded, the heart-sounds are heard posteriorly better than after pulmonary respiration has begun.

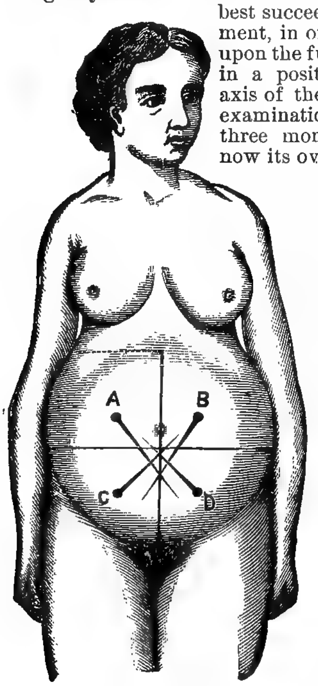

FIG. 3089.

As in the great majority of cases the head is in the lower part of the uterus, the fœtal heart-sounds will be heard most distinctly at some point below a transverse line upon the abdomen passing through the umbilicus. But still more, as in by far the greater number of instances the occiput of the fœtus is in the left side of the pelvis, usually directed toward the left ilio-pectineal eminence, these sounds are most frequently heard with the greatest distinctness upon the left lower of the four spaces into which the abdomen of the mother is supposed to be divided (see Fig. 3089), and usually at a point corresponding to the middle of a line drawn from the umbilicus to the left ilio-pectineal eminence. But if not heard satisfactorily at this place, or in its vicinity, corresponding positions upon the opposite side should be tried. All these failing, the two upper divisions should be examined, for the head, instead of being below, may be above—in other words, there is a pelvic presentation. So much of an explanation seemed necessary, though in consequence of it there is suggested a part of the diagnosis of presentation by this means, in regard to the parts of the abdominal wall to which the stethoscope should be applied in listening for the fœtal heart. The mean frequency of the pulsations of the fœtal heart is, according to some, 140, but according to others, 135; temporary variations, not only in the frequency, but also in the force, of these pulsations are common. The sound is double and rhythmic ; the first bruit is the clearer and more distinct ; a brief pause ensues, and the second is heard, which is followed by a longer interval before the double bruit is repeated.

The uterine souffle is usually heard best at the lower part of the uterus and at its sides, especially the left, which, for reasons previously given, is brought nearer the anterior abdominal wall. This sound is synchronous with the mother's pulse, but without shock ; it is somewhat similar to the sound heard when the stethoscope is applied to a varicose aneurism, but it varies with the pressure made by the instrument, with uterine contractions, and from one time to another, and with the different parts examined, and it is usually not harsh. It may be heard earlier than the sounds of the fœtal heart, in some cases at the beginning of the third month. But it is not a conclusive, only a probable, proof of pregnancy. This, as well as the fact that the placenta is foreign to its production, is proved by the following

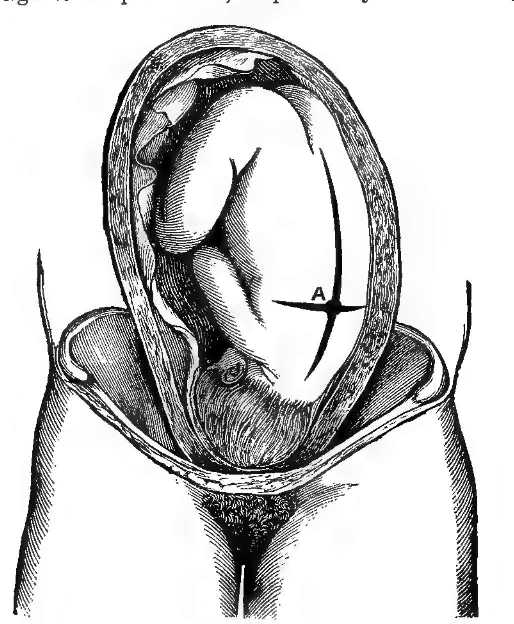

FIG. 3090.

facts : It may be heard in many cases in which the uterus is greatly increased in size from fibroid disease ; it is also heard, in nine cases out of ten, two to three days after labor.

The conclusive proofs of pregnancy are hearing the sounds of the fœtal heart, feeling—possibly, also, seeing —fœtal movements, and recognizing the fœtus by palpation.

Diagnosis of Multiple Pregnancy.—Practically, this discussion may be limited to the diagnosis of twins in the uterus, for the other varieties of pluriparous pregnancy are comparatively very rare. Among the probable signs are greater development of the uterus than in single pregnancy; this development is unsymmetrical, a vertical furrow dividing the organ apparently in two parts ; the abdomen appears to be especially distended at the sides ; fœtal movements are observed at different parts of the uterus, and, finally, the accidents of pregnancy are more frequently observed. The subjoined illustrations from Budin show how fallacious some of the proofs of twin pregnancy may be. In the first the positions usually occupied by the fœtuses are given ; both may present by the head, or both by the pelvis, or one by the head and the other by the pelvis ; but whatever the presentations, the fœtuses are usually side by side. But in

the second drawing one fœtus is in front, and in the third, one is above the other.

The only certain proofs of twin pregnancy are given by abdominal palpation and auscultation. Thus, by the

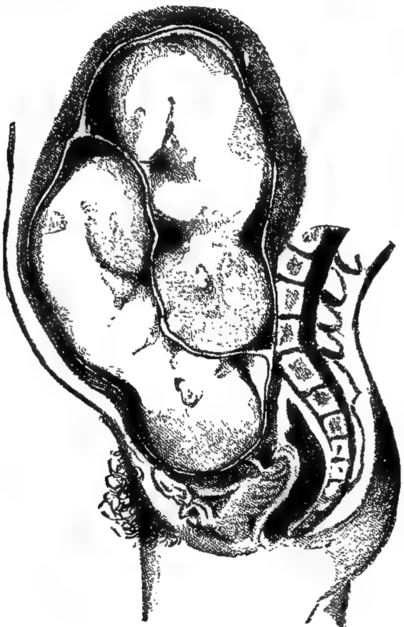

Fig. 3091.

former two heads may be felt in different parts of the uterus, and by the latter two fœtal hearts are heard, with maxima of intensity in different parts, also, of the organ. These sounds differ in frequency; the difference may be

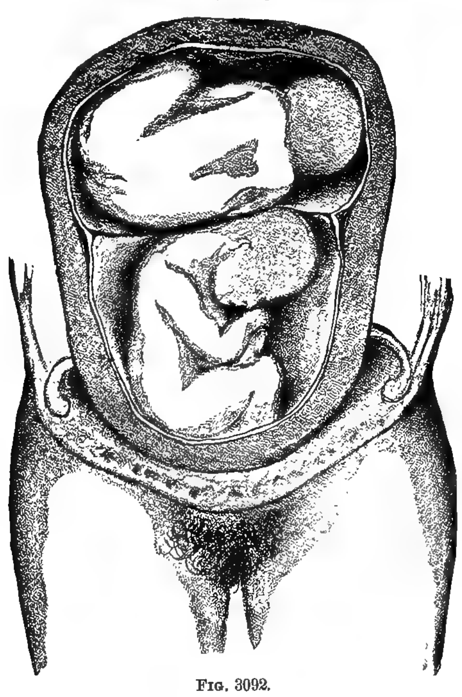

Fig. 3092.

only six or eight, or it may be ten or fifteen, but it is always present.

It should be remembered, however, that very great difficulty in making the diagnosis of twin pregnancy by auscultation will be presented in those cases in which the twins occupy the unusual positions as given in Figs. 3091 and 3092.

Differential Diagnosis of Pregnancy.—It is important to

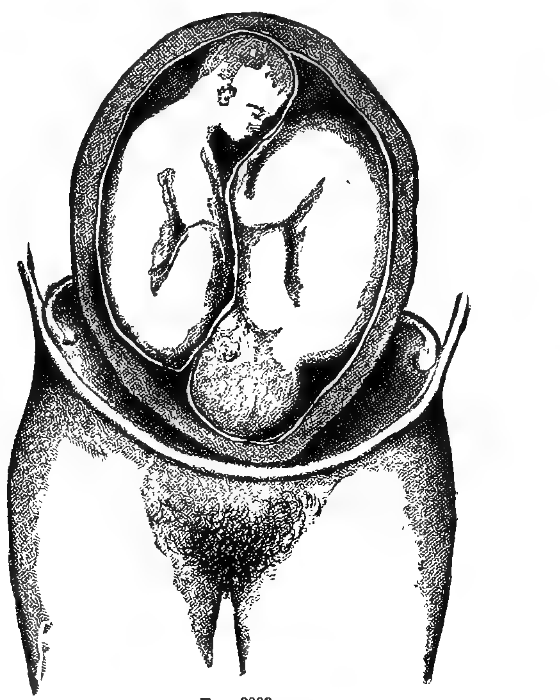

Fig. 3093.

refer to some pathological conditions which may be confounded with pregnancy, and briefly state the means by which error may be avoided. *Hæmatometra:* The enlargement of the uterus is slower, and occurs by sud-

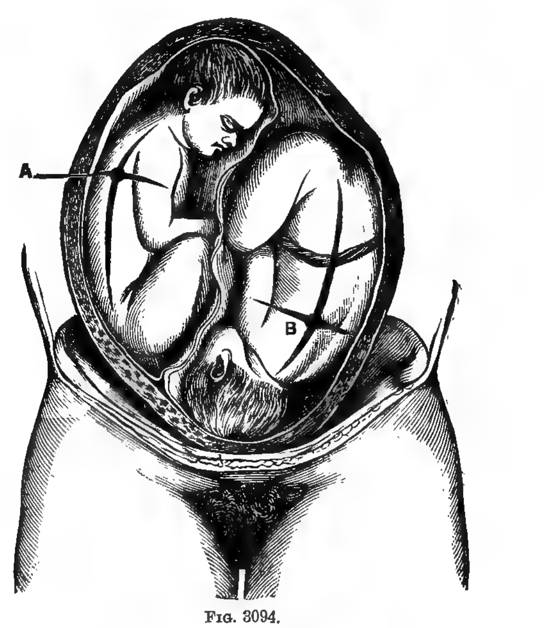

Fig. 3094.

den, not by gradual, increase, and this sudden increase is at more or less regular intervals. Neither vaginal nor abdominal ballottement is possible, and obstetric palpation and auscultation give negative results. *Uterine*

Fibroids: These are slower in development, and the uterus is hard instead of elastic, and generally irregular in form; menstruation, instead of being absent, is usually abnormal, there being menorrhagia, and there may be likewise metrorrhagia; by vaginal touch, absence of the changes in the cervix and os characteristic of pregnancy, often, too, some portion of the hard, irregular fibroid, may be felt; abdominal palpation and auscultation give negative results, except that by the latter the uterine souffle may in many cases be recognized. *Ovarian Tumor:* Usually slower in development, and if of considerable size, marked impairment of general health with considerable emaciation; the history of the growth, if it can be obtained, shows that the enlargement, instead of being at first median, was upon one or the other side; menstruation usually not absent unless the health has been greatly deteriorated; marked fluctuation in most cases when the tumor has attained considerable size; absence of proofs of pregnancy upon palpation and auscultation; and vaginal examination will in most cases be able to prove displacement, but no material enlargement of the uterus.

Uterus Enlarged by Chronic Parenchymatous Metritis.—Menstruation may be irregular, but there is not absolute amenorrhœa; the uterine wall, though somewhat softened, is not elastic and yielding as in pregnancy, and moreover it is sensitive, pain being caused upon pressure, which is not observed when pressing the gravid organ.

Accumulation of fat in the abdominal walls, ascites, tumors of the spleen, need only be mentioned in order that the practitioner may be put upon his guard against error from any of these sources.

It should be remembered that in all doubtful cases time is one of the most important elements of diagnosis; if a woman be pregnant, the fact will become clearer from day to day, for unequivocal signs of the condition will surely come. Therefore he is wisest who waits in such cases until he knows, either by the presence or the absence of these certain proofs, before he gives an opinion, and not he who risks a happy guess, or draws a conclusion from an average of probabilities.

THE HYGIENE OF PREGNANCY.—This includes attention to diet and the condition of the digestive organs, exercise, rest, clothing, sleep, the care of the breasts, and the condition of the mind. In the early months of pregnancy, it is not unusual for the irritability of the stomach to cause lessened desire for food, or possibly the appetite may crave some unusual article of diet; each condition must be considered and respected in the choice of aliments, and in directing the quantity. In some cases the morning-sickness is lessened by having the patient take her breakfast in bed, and not rise until an hour or two after. Generally, in the fourth month gastric disorder disappears, and the appetite is good; digestible and nutritious food, both animal and vegetable, may be taken, and, so far as possible, dietetic means used for the prevention of constipation. As in the ascension of the uterus in the latter months it comes to press upon the stomach, the meals should not be so abundant, but more frequent, and especial care should be taken not to eat heartily in the evening. If the constipation is not relieved by diet, an evacuation should be secured each day by a Seidlitz powder, Hunyadi, compound licorice powder, calcined magnesia, or some similar means.

Care must be taken that the clothing does not compress the abdomen or chest, and it ought to be suitable for the season; especially ought the pregnant woman to avoid being chilled, lest an annoying bronchitis, for example, or a serious nephritis with albuminuria, result from sudden suppression of perspiration. Moderate exercise will be useful, but that which fatigues or is violent, such as dancing, riding on horseback, or over rough roads, must be avoided. Long journeys by sea or land ought, if possible, to be postponed; the fatigue, the excitement, the constant jarring for several days consecutively on a railway train, for example, and the possible dangers and accidents belonging to travel in general, present strong arguments in favor of the advice just given. So, too, fresh air is especially necessary for the pregnant woman—she is breathing for two, and therefore must not be in crowded or badly ventilated rooms. The pregnant woman should observe regular hours of sleep, and it is also well for her to have a brief rest during a part of each day, lying down even if she does not sleep. A warm bath may be taken as usual, but hot baths, especially if frequent and prolonged, may cause abortion; sea-bathing, unless the water is quite warm, is not advisable, and when such baths are taken they must be without great exercise, as in swimming, and they ought to be brief.

The belief held by many philosophers as far back as Plato, and also by many eminent physicians as well as by the public, is becoming stronger, that the condition of the mother's mind has an important influence upon her unborn child; not only is it held that certain deformities may result from maternal impressions, but modifications of the intellectual and moral character, as manifested in after years, may have their origin in the mental state of the pregnant woman. Hence the importance of the prospective mother preserving an equable condition of mind, and as cheerful a disposition as possible; she should be carefully guarded against all injurious influences, and exposure to perils and to painful sights, and there ought to be thrown around her all protecting care and thoughtful kindness.

Sexual intercourse during pregnancy is utterly unnatural; it is a frequent cause of abortions; it is probably regarded with indifference or abhorrence by most women, and is without any moral justification. Many pagan nations have not only condemned this violation of natural law, but coupled severe punishment with the condemnation.

All compression of the mammary glands must be avoided; the nipples especially should be given ample room for their development, and if retracted they ought to be drawn out by means of the thumb and finger for a few minutes each day, and in the intervals a nipple-shield may be worn over them for a time. It is customary to endeavor to harden the skin, so as to prevent the formation of fissures and abrasions from nursing, by washing the nipple each day with alcohol holding in suspension or solution an active astringent. I have for some time protested against this practice, on the ground that the alcohol dissolves the sebaceous secretion with which nature has so abundantly supplied these organs, and which is their best protection from the injurious contact of fluids; even if the skin may be hardened by alcohol or an astringent, nature intended it to be soft and pliable, and not harsh and resistant, and consequently much more liable to be fissured. Therefore, let me advise, instead of the time-honored applications, scrupulous cleanliness of the nipples, the daily washing to be followed by bathing them gently with cologne or tincture of arnica and water, and at night the application of a little cocoa-butter. Delore suggests daily exposure of the nipple to the air as a means of rendering it less liable to become diseased during lactation. Certainly, if the exhibition of as much of the mammary glands as is made by some fashionable women at balls or parties has any justification, it would be in the fact that these women are pregnant, and are preparing for one of the most important duties of motherhood.

PROFESSIONAL CARE DURING PREGNANCY.—The obstetrician should see a woman from time to time during her pregnancy, giving her such instruction and advice as her condition may require. During the last three months, earlier if certain symptoms to be presented hereafter arise, it is important that the state of the renal functions should be learned, more especially as to the presence of albumen in the urine; once in one or at most in two weeks, the condition of the urine should be ascertained by chemical, and if necessary by microscopical, examination.

It would be better too, if at least an external examination were made when the fœtus has become viable, so as to ascertain the position which it occupies in the uterus, and the presence or absence of any neoplasms of the organ of gestation, or of organs adjacent, which may interfere with labor at the normal time. Some cases, too, may

require measurements of the pelvis to be made, especially in a primigravida, or in a woman whose previous labors have been difficult, requiring artificial means for the removal of the child, or in whom possibly the delivery was spontaneous, the child, however, dying in the labor, from the delay and difficulty of the process.

THE PATHOLOGY OF PREGNANCY.—The pathology of pregnancy includes, first, those diseases which are exaggerations of physiological conditions belonging to the pregnant condition, or caused by it; second, diseases beginning before pregnancy, or accidentally occurring during it, that is intercurrent, and which may be modified by the pregnant state or may affect it, and traumatisms, including injuries and surgical operations; third, affections of the sexual organs; and, fourth, maladies of the ovum. These classes will be now briefly considered in their order, omitting, however, from this presentation any of the diseases embraced in this class that are discussed elsewhere in this work.

Hyperemesis.—The morning-sickness of pregnancy, in its ordinary form, has been previously mentioned, and we are now concerned with that exaggeration of the disorder known as hyperemesis, or as the uncontrollable, incoercible, or pernicious vomiting of pregnancy. In about two-thirds of the cases this disease is first manifested before the end of the third month. Usually there is a gradual transition, from the ordinary nausea and vomiting to the grave form of the disorder, when the patient rejects the simplest food or drink, very soon after taking it, and then a part only of the food is vomited; in some cases, however, there is immediate vomiting—for example, simply a little cold water is thrown up immediately after it is swallowed, but more frequently it is retained until it becomes warm. Apparently the most trivial causes will excite vomiting, such as an attempt to sit up, or changing from one position to another, for example, from the back to the side, or when a reverse movement is made. The patient rapidly emaciates, the urine becomes scanty, may contain albumen, and is high-colored; there is in some cases an abundant secretion of saliva, and usually anorexia is present—in part probably from the patient's knowing that taking food will be followed by vomiting.

With the continuance of the disorder the symptoms become graver, and that which has been described as the second stage occurs. The emaciation makes rapid progress, and the patient becomes more exhausted, fainting, it may be, upon so slight exertion as sitting up in bed; the gums may be swollen, the teeth covered with sordes, and the breath offensive; the pulse is 120 or more a minute, and the thirst excessive. Older observers, without the proof of thermometric facts, described this stage as febrile, the conclusion being derived from the frequency of the pulse; but some recent observations do not prove a marked increase in the temperature. The third period soon follows. Now the vomiting ceases, but there are disordered vision and hearing, and often intense neuralgic pains; the pulse may be 140 a minute; mental disorder is shown in hallucination and delirium, and coma closes the scene.

The disease is not always steadily progressive, but presents, it may be, from time to time remissions, consequent, for example, upon a change of scene, or upon some new article of food or of drink. I have known one instance in which the vomiting ceased for some days from drinking lager-beer. Cazeaux quotes from Dubois an instance of grave vomiting in pregnancy, in which the disease disappeared after a violent attack of diarrhœa, and another in which a powerful mental impression, the husband of the patient gravely suffering from strangulated hernia, had a similar effect.

Among causes of obstinate vomiting in pregnancy are displacements of the uterus, inflammation of the cervix, adhesions of the membranes at the internal os, rigidity of the muscular fibres of the uterus not permitting ready dilatation, circumscribed inflammation of the organ, and inflammation of structures adjacent to it; Lebert and Rosenthal refer the disorder in some cases to partial manifestations of a general nerve inanition.

Post-mortem examinations have shown disease of different organs, more especially of the stomach—ulceration and cancer, for example—but, as Tarnier observes, it is impossible to describe the pathological anatomy of the disease, and while actual alterations in certain organs have been found, there is no constancy in these facts, and in some instances no lesion can be discovered.

Guéniot found that in 118 cases the recovery took place in 72, and 46 died; of the 72 who recovered, 42 either spontaneously aborted, or else premature labor or abortion was induced. Of the 46 who died, 28 did not abort, and 18 had abortion or premature labor induced, or miscarriage was spontaneous.

The treatment is hygienic, medical, or obstetrical. A change of residence, as from the city to the country, an entirely new diet, especially choosing an article of nourishment for which there may be a particular desire. Possibly iced lime-water and milk, or ice-cream may be tolerated and prepare the way for taking other food; effervescent drinks may be employed. Finally, absolute rest may be given the stomach for a time, rectal alimentation being employed. The medicines advised are very many, and by their number testify to the fact that results accomplished are quite uncertain. Among these are tincture of nux vomica, oxalate of cerium, dilute hydrocyanic acid, subnitrate of bismuth, chloroform, or sulphuric ether, each of the two latter given in doses of a few drops with water, or in perles, the various preparations of pepsine, chloral, bromide of potassium, and opium or one of its liquid forms, or morphia. Inhalations of oxygen have occasionally succeeded, and also the use of electricity; recently, too, cocaine has been strongly recommended. The application of ether spray to the epigastrium has been employed; so, too, have Chapman's ice-bags to the spine; a small blister to the epigastrium, in some cases followed by the use of morphia endermically, has relieved some.

Of course a uterine displacement should be corrected; cauterization of the cervix, and the application of belladonna to the vaginal portion has been employed with occasional success; Copeman used digital dilatation of the cervical canal, while others have leeched the cervix.

The obstetric treatment consists in the induction of abortion, or, if the pregnancy has continued until the child is viable, of premature labor. But this grave step is rarely required, and ought not to be undertaken until the usual means for the arrest of the disease have been vainly tried, and until the condition of the patient is such that her life is in imminent peril from the disease; it should also be borne in mind, that while in the majority of cases the vomiting ceases when the uterus is emptied, or soon after, there are some in which no such happy result follows; and, on the other hand, that cases now and then are seen in which the disorder is most grave and has persisted notwithstanding well-directed remedies, so that the practitioner despairs of a favorable ending, and yet, with some slight dietetic or medicinal change sudden improvement takes place and the disease ceases. The responsibility of ending the pregnancy ought to be shared with a reliable confrère.

Finally, the induction of abortion is not to be thought of if the patient has passed into the third stage of the disease, for then death is inevitable, and may be hastened by this treatment, bringing reproach alike upon the method and the art.

Serous Cachexia or Hydræmia.—Among the exaggerations of the physiological changes of pregnancy is that condition which Stoltz, and before him, according to Tarnier, Baudelocque, the nephew, and Lasserre, called a serous cachexia; Kiwisch gave the name of serous plethora to those blood changes consisting of increase of the quantity of blood and of its water. Stoltz speaks of the serous cachexia as an exaggerated hydræmia.

Patients suffering from this condition may have œdema of the lower limbs only, but frequently the serous effusion involves the connective tissue of the external generative organs, the upper limbs, the trunk, and the face; there may also be effusion of serum in the great serous cavities. If there should be disease of the heart the

symptoms are more serious. Nevertheless, notwithstanding this general or localized dropsy, the urine is entirely free from, or contains only a trace of, albumen.

The treatment should consist in rest, nutritious diet, the administration of tonics, especially of iron, the hot bath, diuretics, and occasional mild derivation to the intestinal canal. Tarnier attaches great importance to milk diet. In some cases punctures of the swollen external genitals or of the œdematous lower limbs may be advisable, but should not be made unless the necessity be urgent, lest gangrene ensue. If there is great accumulation of serum in either the thoracic or the abdominal cavity, thoracentesis or abdominal paracentesis may be employed without hesitation. Charles has recently recorded in the *Journal d'Accouchements* a fatal result in a woman near the close of her pregnancy, in whom the most prominent symptom was this hydræmia.

Anæmia.—Those who suffer from hydræmia are anæmic, but there may be an anæmia not marked by serous effusions, or, at least, there is only a moderate œdema, more especially of the lower limbs. Such a condition creates a liability to post-partum hæmorrhage, and should be corrected by attention to nutrition, and by the use of tonics, especially of iron preparations.

Pernicious Anæmia.—In addition to the simple form of anæmia just mentioned, there is a grave manifestation of the disease, occurring comparatively rarely, and known as pernicious or progressive anæmia. Twenty-six years ago this disorder was described by Gusserow, but some time before this cases of the disease were reported and many others observed, but not published; in this country, for example, practitioners, more than thirty years since, met with instances of the disease presenting the grave symptoms which Gusserow and others afterward described, and which, by a sort of general consent, was given the title of puerperal anæmia.

The etiology of the affection is obscure; in some cases those affected have suffered from malaria, or were exhausted by rapidly recurring pregnancies, by obstinate vomiting, or by insufficient food; hæmorrhage, profound mental shock, and diarrhœa were also considered causes. Nevertheless, cases of the disease have occurred in which none of these factors were present.

Generally the disease begins gradually. The skin of the face grows paler and paler, and has a waxy appearance; in some cases the skin has a yellowish hue, but there is no emaciation, the weight, for a time at least, being retained; but after a time fever occurs, and then there is loss of flesh. Often there is anorexia. The more prominent general symptoms are palpitation of the heart, fainting, syncope, and headache; frequently sleeplessness is observed, but in some cases drowsiness. Hæmorrhages are not unusual, and the gums may be spongy and swollen, as in scorbutus.

Abortion or premature labor is a common occurrence, and in the latter case the fœtus is usually found to be dead. A fatal issue occurred in the majority of cases observed, though in some it was delayed for months.

In regard to the treatment, remedies addressed to the anæmic condition are, of course, indicated, but it is not necessary to enumerate them. A more important question arises in reference to the induction of abortion or of premature labor. Interruption of pregnancy was advocated by Gusserow, has received the indorsement of Charpentier, and more recently of Zweifel, but, on the other hand, is rejected by Kleinwächter, because of its hastening the commonly fatal termination of the disease. Chiara advocates an early induction of premature labor, or even of abortion, as in the obstinate vomiting of pregnancy. Tarnier observes that the epoch of intervention presents a grave question which is difficult to decide.

Varicose Veins.—Varicose veins of the lower limbs, or of the external genitals, or of the vagina, of the rectum and anus, are not very uncommon in pregnancy, though authors widely differ in their statements as to the frequency of this accident. For example, Budin asserts that twenty to thirty per cent. of pregnant women suffer from varicose veins, while Cazin makes the number one in twenty-one; and my own observations, made in the Philadelphia Hospital, are much more nearly in accord with the latter than with the former statement.

Among the alleged causes of varicose veins are increased quantity and changed character of the blood, gravitation, greater vascular tension, and pressure upon intra-abdominal veins by the enlarged uterus. Tarnier states that some authors have added to modifications in the circulatory apparatus, in explaining the occurrence of varices, those which take place in the nervous system under the influence of pregnancy. It must be confessed, however, that this etiology is not very obvious. Rupture of a varix in pregnancy may cause a rapidly mortal hæmorrhage, while such rupture in a varix of the vulva or vagina, taking place in labor, may result in the formation of a thrombus or hæmatoma, seriously interfering with the delivery of the child.

If the varicosities be large, all straining, or lifting heavy weights, taking long walks, and even being for a considerable time in the erect position, should be avoided; the subject must lie down a part of each day; moderate compression with a properly applied flannel bandage to an affected limb, especially if there be much œdema, as there frequently is, will be useful. The patient ought to be taught, in case there is threatened rupture of a varix, how to arrest hæmorrhage from it by direct compression.

Albuminuria.—Albuminuria is probably present in five to ten per cent. of pregnant women, although Dumas, uniting the statistics of Hippolyte, Abeille, Möricke, and Petit, finds that one in five or six thus suffers; Tarnier refers to the results recently published by Negri, Doléris, and Poucy, showing that the proportion of albuminurics is about five per cent.

A woman suffering with albuminuria may become pregnant, or another, being pregnant, may be attacked with nephritis; but in either case the albuminuria is an accident, independent of the pregnancy. On the other hand, however, there may be a nephritis which results from the pregnant state, the urine showing the presence of albumen, hyaline casts, and renal epithelium; but the disease disappears after the pregnancy. Various explanations have been given of the nephritis of pregnancy. Among these are the renal disorder which results from the increased work thrown upon the kidneys by the pregnant state, the greater vascular tension, pressure upon the renal veins by the enlarged uterus, similar pressure upon the ureters, and finally from reflex irritation, this irritation arising from the uterus and affecting the renal circulation and secretion. Leyden (*Zeitschrift für klin. Med.*, 1886) maintains that the lesions of the kidneys found in pregnancy nephritis do not correspond either to venous stasis or to acute nephritis, and attributes great importance in their production to arterial anæmia. According to him, this anæmia results from hindrance to circulation in the abdomen caused by the enlarged uterus, this hindrance increasing with the greater size of the organ of gestation. The cause acts mechanically by diminishing the quantity of urine, and hence albuminuria, and dynamically from lessening the supply of oxygen, and hence fatty degeneration of the kidney. Zweifel (*Lehrbuch der Geburtshülfe*, 1887) holds that of the many theories advanced in explanation of the disorder, only two deserve special mention, and yet neither has been proved. The first was proposed by Frerichs, and accepted by Bamberger, Leitzmann, Rosenstein, Lange, Hohl, Möricke, and others. According to this theory the renal changes are the result of increased intra-abdominal pressure, preventing the escape of the venous blood from the kidney, and thus causing engorgement of the organ. The other theory, that of Halbertsma, explains all the facts as resulting from pressure of the enlarged uterus upon the ureters. The former is accepted by Zweifel.

It is unnecessary to state the usual manifestations of albuminuria in pregnancy, nor the means by which a diagnosis is made. The most serious possible result is eclampsia; for while the majority of albuminurics are not eclamptic, it is very rare for eclampsia to occur in pregnancy unless the patient has albuminuria. Winter has recently called attention to premature detachment of

the placenta as a not uncommon accident in nephritic patients.

The treatment of albuminuria in pregnancy is governed by the same rules that apply to the management of the disease in the non-pregnant, except, probably, as advised by Tarnier, an absolute milk-diet, if the quantity of albumen in the urine be great, should be strictly enforced, and in some cases it gives remarkably good results; in some patients, the induction of premature labor or even of abortion may be clearly indicated.

Cardiac Disease.—It has been claimed that disease of the heart may result from pregnancy. Thus, admitting a normal hypertrophy of the organ caused by the pregnant condition, it is asserted that, as a consequence of rapidly recurring pregnancies, an ordinarily transitory hypertrophy becomes permanent. But this is only hypothetical. Further, as stated by Tarnier, Ollivier claims that subacute and chronic endocarditis may originate solely under the influence of pregnancy. However these questions may be decided, the obstetrician is concerned almost exclusively with cardiac disease which was present when the pregnancy occurred. Undoubtedly the pregnant woman, from the fact of her condition, is more liable to suffering, and even to danger, if she has valvular disease; the pregnancy becomes a complication in many cases, though not necessarily in all. Budin and others have shown that cardiopathics are peculiarly liable to abortion; Porak found that in 214 women who had disease of the heart, the pregnancy continued until term in only 126, while 88 aborted, or had premature labor. Whether premature or mature labor, or miscarriage occur, there is an increased liability to post-partum hæmorrhage. The treatment during pregnancy does not ordinarily differ from that required by cardiac disease in the non-pregnant condition. In some cases the induction of abortion or of premature labor may be indicated by the danger to the life of the mother.

Relaxation of the Pelvic Joints.—Some swelling and softening of the pelvic joints is one of the normal phenomena of pregnancy, but should these be excessive the mobility of the pelvic bones may become so great that it is impossible for the patient to walk, and, indeed, any movement of these bones may be attended with great suffering. The joint most liable to be affected by this abnormal relaxation is the pubic. The relaxation usually occurs in the latter half of pregnancy, but Moreau mentioned a case in which it appeared in the second month, and in this patient it continued for more than two years after delivery. Having begun, it usually increases until the end of pregnancy, when it gradually lessens and disappears in most cases. The most important treatment is rest; the more exercise is urged upon the patient, the more miserable she becomes through suffering and aggravation of the disorder. A prolonged rest, too, is required after labor, and when the patient gets up the immobility of the bones should be secured by a suitable apparatus. Barker states that in all cases he has seen this immobility has been effected by a little ingenuity in making and adapting a hip-binder of very strong, coarse cloth.

Neuroses.—Different nervous affections may occur in pregnancy, some of them indeed depending upon the pregnant condition. Among the latter may be mentioned neuralgic disorders, especially of the teeth.

Hysteria.—In most cases of hysteria the disease antedates the pregnancy, but in a few it seems to originate from it. While in a few cases hysteria has disappeared during pregnancy, in the majority it continues, sometimes becomes aggravated, and even insanity may follow labor. An interesting fact, observed by many, is that in some instances there is an almost, or quite, total absence of suffering during childbirth.

The treatment of hysteria in a pregnant woman is the same as if she were not pregnant.

Epilepsy.—If an epileptic become pregnant the disease may be mitigated by the pregnancy, but the attacks return with their original severity and frequency of occurrence subsequently; probably, however, a temporary favorable modification occurs in the majority of cases. In the rare instances in which the disease begins in pregnancy, it ceases after labor.

Chorea.—This is not a frequent disorder observed in gestation, for Barnes could find but fifty-six cases which had been published, and Fehling, in 1874, was able to add only twelve to this number. The liability to the disease is greater in primigravidæ than in multigravidæ; previous attacks of the disease create a predisposition to it; it may recur in several successive pregnancies, or be present in the first only. It usually begins in the first half of gestation, continues during the entire subsequent time, and in rare instances during the puerperal state. Wenzel's statistics show the mortality of the disease to be 27.3 per cent., and Spiegelberg found 23 deaths in eighty-four cases. The medical treatment need not be stated, for it is the same as when the disease occurs in the non-pregnant condition. The obstetric treatment, if the child be viable and the usual means for relief have been tried without benefit, and if the choreic movements are violent while the patient's strength is failing, is the induction of labor. Whether cases occur in which abortion is necessary is an undecided question.

Diseases of the Skin.—Duhring calls attention to the fact that in a few cases eczema, herpes, or pruritus may result from the pregnant condition, but they cease as soon as the pregnancy is over, and that chloasma is common; while, on the other hand, chronic affections, as eczema and psoriasis, are often observed to be much better during this period. In rare cases the pruritus is so severe that abortion has occurred. In three patients suffering with the disease who were seen by Cazeaux, the pruritus readily yielded to alkaline baths; Tarnier commends a solution of cocaine. Slocum has reported a case of *hirsuties gestationis.* The woman had been pregnant three times, giving birth to three children at term, "and with each gestation a growth of hair on the sides of the face, and under the chin, started at the beginning of the pregnancy and continued until childbirth, growing to the length of one and a half inch. As the catamenial function returned, the hair fell out, the face assuming its normal smoothness."

Acute Infectious Diseases.—Several observations have been made showing that when the mother suffers from a high temperature, the pulsations of the fœtal heart are increased in frequency and lessened in force, and interruption of pregnancy not unseldom occurs. The experiments of German observers seemed to prove that this interruption was due to the continued elevation of temperature; but the experiments of Charpentier, Doléris, and F. Doré, proved that if the increase was gradual, pregnant animals did not abort, nor was the life of the fœtus in the least compromised. Accepting these results, the conclusion must be, as Charpentier has stated ("Archives de Toxicologie," 1887), that hyperthermia does not exercise an important, only a secondary, influence in the production of abortion and the death of the fœtus, when the mother suffers with grave pyrexia, variola, scarlatina, rubeola, erysipelas, typhoid fever, etc.

The interruption to pregnancy occurring in infectious diseases has also been regarded as resulting from hæmorrhagic endometritis. The investigations of Slavjansky, for example, showed such condition in the cases of pregnant women attacked with cholera. But, on the other hand, Queirel, in his recent studies of the epidemic of cholera at Marseilles, took pains to seek for this endometritis, and he has not found it; he states that hæmorrhages have not occurred either in abortions or in labors, though he has frequently met with uterine inertia. Klotz, of the University of Innsbrück, studying the course of measles in pregnant women, in eleven cases of which there was interruption of pregnancy, endeavored to ascertain the causes of fœtal death not only in measles but in other infectious diseases, and concluded that hæmorrhagic endometritis was not proved anatomically in this disease, in scarlatina, in variola, in erysipelas, or in typhus.

Zweifel gives importance to the action of the "fever-blood" upon the nerve-centres causing uterine action,

great increase of temperature producing, as a rule, uterine contractions.

Probably, however, the most important factor in interrupting the pregnancy is, as asserted by Charpentier, toxæmia, the death of the fœtus resulting from this, and then its discharge from the uterus follows.

Typhoid fever may occur in pregnancy ; this condition, according to the statement of Murchison, and contrary to the opinion of Rokitansky and Niemeyer, furnished no exemption from the disease. In the great majority of cases, though the pregnancy is interrupted, recovery takes place.

Yellow fever is quite as likely to occur, according to Bemiss, in the pregnant as in the non-pregnant, but the liability to the disease is increased by childbed. Still referring to the statements of Bemiss, the liability to death is twice as great in pregnancy and in childbed. If the pregnant woman recovers from yellow fever, and gestation continues, the child is protected from the disease. The last statement certainly points to and strengthens the assertion previously made, that the usual cause of death in acute infectious diseases is toxæmia, that is to say, the specific poison of the disease passes from the maternal to the fœtal blood. It is not admitted that there is even a partial exemption from intermittent fever given by pregnancy ; where facts seem to sustain this view, their probable explanation is found in pregnant women not being so much exposed to the malarial poison. It seems to be tolerably well established that the fœtus may suffer from malarial poisoning, this condition being manifested by regularly recurring paroxysms of convulsive movements ; and in some of these cases the child at birth was found to be suffering from enlarged spleen. The administration of quinine is not forbidden by pregnancy, and if abortion or premature labor occur, the event is not to be attributed to the drug, but to the malarial intoxication ; nevertheless, it is possible that in some women there may be such idiosyncrasy that some other antiperiodic should be employed.

About sixty per cent. of pregnant women abort or have premature labor if attacked by cholera, though the recent statistics of Queirel, including 67 cases, show that in only 29 the pregnancy was arrested. The statistics just referred to also show that when the pregnancy was interrupted, the mortality was about sixty-six per cent., but if it continued, only fifty per cent. The death of the fœtus, probably, is usually due to toxæmia, as previously stated, or it may result from asphyxia.

Curschman claims that pregnancy causes a certain predisposition to variola. In varioloid there is little danger to the mother or to the fœtus, but in variola abortion or premature labor usually occurs, and is followed by the death of the mother. If a pregnant woman has variola, the rule is that the fœtus is also affected, and it may pass through all the stages of the disease in the uterus, but in some cases is born with the disease, and in others may be attacked soon after birth ; very rarely an apparently healthy mother gives birth to a child having variola, and the explanation proposed is that the mother had the disease without the eruption, and thus infected the child.

In some cases successful vaccination of a pregnant woman has rendered the new-born insusceptible to vaccination. Hence there is a stronger argument for vaccinating the pregnant woman if she is liable to be exposed to small-pox.

Scarlatina has been rarely observed in pregnancy. It is very liable to interrupt the pregnancy, and is peculiarly fatal. A similar statement may be made as to rubeola.

Pneumonia is a more frequent disease of the male than of the female, but in the female it has a one-third greater mortality, and is far more dangerous in pregnancy. The pregnant woman, if attacked with the disease, is liable to abort or to have premature labor ; this liability to interruption of the pregnancy is greatest the farther the latter has advanced ; after interruption the patient in most cases dies within two or three days, if recovery does not take place. Some have urged ending the pregnancy by artificial means, but the practice is not generally accepted, most authorities preferring the expectant plan of treatment.

Pleurisy usually terminates favorably, and does not disturb the pregnancy, but if the disease be double, or if bronchitis be associated with it, abortion or premature labor may result. Thoracentesis has been performed upon the pregnant woman without disturbing the gestation.

Jaundice ; Icterus Gravidarum.—This disease may occur in pregnancy in one of two forms—simple or malignant. The first, when it appears in the later months, is attributed by Frerichs to pressure of the enlarged uterus or of the colon distended with fæces, upon the bile-duct ; while Tarnier suggests that there is an icterus peculiar to pregnant women, and Peter regards it as arising from congestion of the liver ; Bedford has suggested that the disease may sometimes be in part due to mental emotions. The prognosis is favorable ; nevertheless, in rare instances that which was apparently the benign form of the affection becomes malignant. The malignant form of the disease, which is seldom seen, is dependent upon acute yellow atrophy of the liver, and usually causes abortion or premature labor, and has a fatal result. There have been occasionally epidemics of jaundice in pregnant women, gestation in many instances being arrested, the majority of those affected dying.

It has been been advised in malignant jaundice that the uterus should be emptied, but this rule has not been adopted ; certainly, if in a case of benign jaundice its future malignant character could be foreseen, the practice would be justifiable. So, too, it has been advised that in case of an outbreak of epidemic jaundice, security for pregnant women not yet attacked might be found in a change of residence.

Traumatism.—This includes injuries, and surgical operations in pregnancy. Very grave injuries have been received by pregnant women, and important surgical operations, such as removal of ovarian tumors, performed, and gestation has continued, while, on the other hand, comparatively trivial injuries have arrested it. According to Cohnstein, penetrating wounds of the abdomen usually arrest the pregnancy, though the uterus may not be injured. Operations upon the genital zone are very liable to disturb the pregnancy. A question of some importance is as to the repair of fractures in the pregnant woman, and a difference of opinion exists, some contending that this repair takes place as promptly as it would if she were not pregnant, while others, among whom Cazeaux and Tarnier may be mentioned, hold that there may be very great delay—the former narrating an instance in which a woman in the second month of pregnancy fractured the tibia, and consolidation failed to occur until after labor at term.

In three cases of gun-shot wounds—one case being reported by each of the following, Richard, Staples, and Hays—involving the uterus, the pregnancy was arrested ; in one a living child was born ; all the mothers recovered.

The simple rule in regard to operations in pregnancy may be founded upon the statement of Sir James Paget, that it would be mere recklessness to operate on a pregnant woman without good cause ; yet, if good cause for operation exists, she may be treated very successfully.

Chronic Infectious Diseases.—The statistics of the late Austin Flint and those of Gaulard show that a large percentage of women become phthisical during pregnancy or lactation. James, however, claims that pregnancy has a favorable effect, but that labor and lactation are undoubtedly injurious ; it would seem impossible to isolate the effects of labor from those of its preceding and following state, and really the conclusion is without practical value, save that the woman who has tuberculosis ought not to nurse her child, and this rule has been clearly shown by previous observations.

Pregnancy in the phthisical is rarely interrupted, even though the woman may be greatly exhausted by the disease ; the disease, when labor is over, usually pursues a more rapid course ; as might be expected, the children born of such mothers are in most cases feeble, and generally die early.

If the physician is consulted, it is his duty to earnestly advise against the marriage of a phthisical subject, whether maiden or woman.

Fournier holds that pregnancy is a complication of syphilis, complicating it by adding to it its own peculiar anæmia, its disposition to neuroses, its disorders of nutrition, etc. Abortion or premature labor is a very common consequence of the disease; thus, out of 414 pregnant women at Lourcine, in only 260 did the pregnancy continue until term. The secondary stage of the disease is that which furnishes the greatest liability to interruption of pregnancy, and from the fourth month to the end of the second year is the period during which a pregnancy is most liable to be arrested.

It is claimed by some, denied by others, that a syphilitic father may beget a syphilitic child, the mother remaining free from disease; yet, according to Fournier, who admits the possibility of direct paternal infection, the probabilities are that the child will not be infected. The most frequent source of infection is the mother. She may be syphilitic before conception, or she may acquire the disease just before, the fecundating being the infecting coition, or, finally, she may acquire syphilis during the pregnancy. Now, in the two first cases the child may be syphilitic; but in the third case, the infection taking place during pregnancy, it has been held that if this occurs after the middle of pregnancy the danger is very slight, and almost none if the mother becomes affected toward the end of normal gestation. Yet Tarnier refers to one instance in which the child was born syphilitic, though the mother did not become infected until the eighth month. The probabilities of the offspring being syphilitic are greatest in those cases in which both the parents are syphilitic. Should a syphilitic woman become pregnant, an antisyphilitic treatment must be employed, and so, too, if she becomes syphilitic during her pregnancy. If she is free from the disease, but is impregnated by a syphilitic man, ought this treatment to be pursued? The answer generally made is, not unless she has previously had pregnancies arrested presumably from syphilis.

Diseases of the Sexual Organs.—Pruritus of the vulva is sometimes met with in pregnant women. The application of a solution of borax in water, or in rose water to which morphia is added, as recommended by Meigs, or of cloths wrung out of hot water, generally gives relief. Other means are brushing the parts with a solution of muriate of cocaine, or of carbolic acid, or of chloral. Tarnier states that he has, in almost all cases, succeeded in relieving the pruritus by the employment of a solution of corrosive sublimate in the following formula: Corrosive sublimate, one part; alcohol, five parts; rose water, twenty, and water, two hundred and twenty-five.

Vegetations of the vulva may appear during pregnancy, and usually spontaneously disappear when the pregnancy is over. While, probably, in the majority of cases these growths are specific in origin, yet in some they may not be. Unless they are large and occupy so much space that they will interfere with the expulsion of the fœtus, active treatment during pregnancy is not advisable, for excision would be attended with considerable hæmorrhage, and besides the growths would soon be reproduced. The affected surfaces should be, so far as practicable, separated and kept clean; disinfectant and astringent solutions are to be applied. Tarnier speaks favorably of the application of a strong mixture of tannin and water, and Charpentier has seen the growths disappear by isolating the affected parts, and applying compresses dipped in Labarraque's solution.

Prolapse of the vagina, especially if cystocele be associated with it, may require the use of astringent injections and wearing an elastic ring pessary; for the latter, should it cause pain, a tampon of prepared wool to which a string is attached, dipped in a mixture of glycerine and tannin, may be worn during the day and removed when the woman retires.

Different forms of vaginitis may affect the pregnant woman, the chief of these being simple, granular, and specific; the two latter may be associated. In simple vaginitis, the most marked symptom of which is a leucorrheal discharge, bathing, cleanliness, antiseptic and mild astringent injections twice a day, will be useful; vaginal injections in pregnancy should be warm or tepid, and the fluid is to be used as a wash, not as a douche. Granular vaginitis, first described by Deville, in 1844, is characterized by the presence upon the surface of the vagina, especially at its upper part, of elevations about the size of a hemp-seed, so that the examining finger touches a rough, grater-like tissue, and by rather a profuse yellowish discharge which irritates the parts with which it comes in contact in passing out of the vagina. In addition to the means applicable to simple vaginitis, every other day a cotton or wool tampon, containing half a teaspoonful of powdered alum and the same quantity of subnitrate of bismuth, may be placed in the vagina; instead of this dry tampon one made of cotton first dipped in glycerine, and its surface freely covered with boric acid, may be employed; in either case the tampon is removed after twelve hours. Nitrate of silver injections also prove useful, or the diseased surface being exposed by a speculum, and then cleansed, is brushed over with the solution. Gonorrhœal inflammation of the vagina demands treatment in the interest of the child and of the mother, for the former, during its passage through the vagina may, by the contact of the infectious matter with the conjunctivæ, subsequently have a specific conjunctivitis, or the latter, from extension of the vaginitis after labor, have a salpingitis. Nitrate of silver injections here, too, are useful, but probably the most valuable remedy is corrosive sublimate, an injection of one part to three thousand of water being used at least twice a day.

In 1871 Winckel first described a form of vaginitis characterized by the presence upon the vaginal surface of a large number of transparent cysts, fifteen or twenty often being found upon a part the size of a dollar; most of these cysts contained gas, and when punctured collapsed with a sound quite audible; there was usually hypersecretion; he gave the disease the name of colpohyperplasia cystica.

Painless contractions of the uterus as one of the normal phenomena of pregnancy have been described; but under certain circumstances these contractions cause more or less severe suffering. If we admit with Wigand the existence of uterine rheumatism, the explanation of such suffering is in many cases quite simple, for it is the same in contractions of the uterine muscle as it is in the exercise of voluntary muscles affected by rheumatism. But most authorities do not regard the existence of uterine rheumatism as proved. The hypothesis of uterine neuralgia, or that of a metritis, has been suggested, or else we may say that in some women the gravid uterus is peculiarly sensitive to pressure, whether that be made from within or from without, as caused by fœtal movements, or by placing the hand upon the abdomen. There is, however, a form of intermittent pain in the gravid uterus resulting from injury, which apparently threatens premature labor or abortion, though neither occurs; and which has not been the subject of special consideration; two cases of this kind I have recently met with, one in hospital, the other in private practice. In the former a multigravida, at the beginning of the seventh month of pregnancy, fell, striking the front part of the abdomen upon a stove. As painful contractions of the uterus succeeded it was at first supposed labor was at hand, but there was no increased vaginal discharge, no effacement of the uterine neck, and no dilatation of the os. Though the uterine soreness and the painful contractions continued for two or three weeks, the pregnancy went to term, and the labor was normal. In the second case a multigravida, at the beginning of the seventh month, was lying in bed upon her back; one of her children, aged two years, was in the bed, and in his romping fell so that his head struck one side of the uterus. For several days she suffered severe intermittent pain in the uterus, but this pain, though the entire organ contracted during it, was referred exclusively to the side which had been struck. In each case the explanation of the suffering was that the normal and ordinarily painless contractions of pregnancy became painful because of injury to the organ. The treatment of such cases will be rest, opium, and the ap-

plication of warm compresses to the abdomen; occasionally a mild counter-irritant may be required.

Various positional disorders of the gravid uterus may occur—prolapse, anteversion, anteflexion, retroversion, and retroflexion—the gravest of these being complete

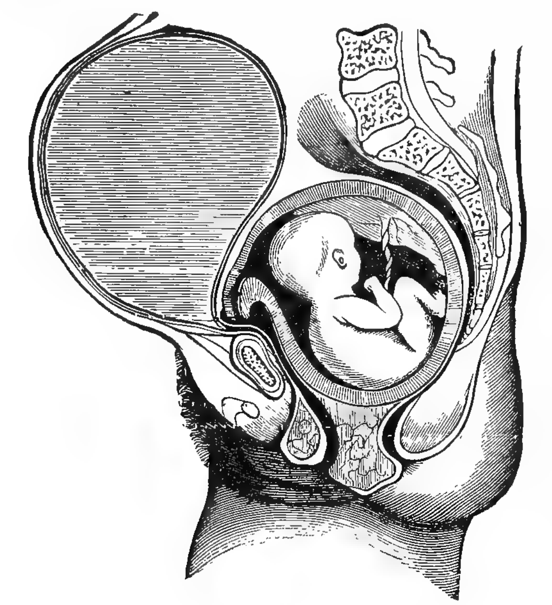

Fig. 3095.

prolapse and the posterior displacements; in addition to these there may be herniæ of the organ.

In prolapse of the uterus the organ may descend to the pelvic floor, and may partially or entirely protrude from the vulvar orifice; should the latter occur the prolapse is called complete. In most cases the patients are multigravidæ; in some the accident occurs gradually, in others suddenly, in consequence of a violent effort, as lifting a heavy weight; and in rare cases impregnation of a prolapsed uterus has taken place; there have been instances where prolapse of the uterus has occurred during labor; in some of these the labor was spontaneous, in others it was artificial, the accident taking place, for example, during extraction with the forceps.

Visual, digital, and bimanual examination will readily recognize this positional disorder of the uterus and its degree, care being taken to avoid mistaking hypertrophic elongation of the cervix for this displacement.

The consequences of prolapse of the gravid uterus may be very serious. There is great liability to interruption of the pregnancy, and in rare instances incarceration of the organ occurs, having similar grave results to those which will be referred to in connection with this accident in posterior displacements.

The question as to whether the pregnancy in a completely prolapsed uterus can continue until term, has received different answers, eminent German authorities, such as Schroeder, Gusserow, and Zweifel, asserting that no authentic case of this kind has ever been reported; while some French authorities, among whom may be mentioned Charpentier and Tarnier, hold the opposite; the statement of the former seems the more probable.

If prolapse occur in pregnancy an effort should be made to restore the uterus to its normal position and to keep it there; after its restoration the patient ought to remain in the horizontal position until danger of the recurrence of the accident is improbable. If the organ be irreducible, and serious difficulties are present, especially incarceration, there must be no hesitation in producing abortion, and after this has occurred the restoration of the organ is to be made.

Anteversion, or anteflexion, of the pregnant uterus is a less frequent, and usually a less grave, accident than the corresponding posterior positional disorders. Should either of the first two accidents occur in the early months of pregnancy, the progress of gestation gradually rectifies it in almost all cases. In the late months of pregnancy there may be in the multigravida, in consequence of great relaxation of the abdominal wall, marked projection of the uterus in front, causing the woman more or less inconvenience and discomfort; the relaxation may be so great that the anterior wall rests upon the thighs when the subject is standing. Lying upon the back as much as possible, and, when the woman is up, wearing a suitably applied bandage, constitute the proper treatment of this accident in the latter part of pregnancy.

Should incarceration of the gravid anteverted or anteflexed uterus happen, an accident possible only in the early months, and which has a predisposing cause in increase of the antero-posterior diameters of the pelvis, the fundus of the uterus is fixed behind the pubic joint; but manual reduction can usually be readily effected. For this reduction the patient is placed in a horizontal position, the hips somewhat higher than the head; then an effort is made, by drawing upon the cervix and pressing upon the anterior wall of the uterus, near the fundus, to restore the organ to its normal position; or pressure may be made with the index and medius introduced into the vagina upon the body of the uterus. "Godefroy placed the index of one hand in the vagina, the other in the rectum, and effected reduction by pressure in opposite directions; while Moreau drew the neck down by a finger in the vagina, and pushed up the fundus by means of a sound in the bladder."

Posterior version or flexion of the gravid uterus is a more frequent and grave disorder, if it should not be rectified by nature or by art. These names are frequently used synonymously, and indeed it is asserted that a pure retroversion of the gravid uterus is rarely met with, some flexion usually being combined with it. Nevertheless, it

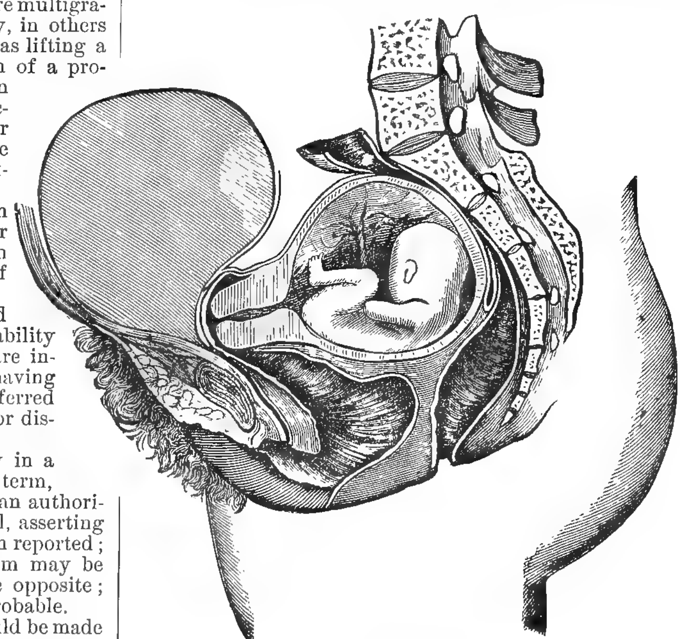

Fig. 3096.

is probable that a woman whose uterus is retroverted rarely becomes pregnant, and hence, if the gravid uterus is found retroverted the accident almost certainly occurred after impregnation; and on the other hand, a

woman with retroflexed uterus may become pregnant more frequently than one whose uterus is in normal position, because the deviation is frequently the cause of abortion. In retroversion the axis of the cervix corresponds with that of the body of the organ, while in retroflexion it forms an angle—acute, right, or obtuse—with the uterine axis. The preceding illustrations, the first of flexion, and the second of version, show the essential difference between the two. In regard to retroversion of the gravid uterus, there has been much dispute as to whether the deviation is sudden or gradual, and as to whether distention of the bladder is cause or consequence. It may be admitted that each form of deviation can occur, that is, it may be sudden or gradual, and that distention of the bladder is occasionally a cause, while in all cases it is one of the gravest consequences of the change of position.

In the majority of cases of these positional disorders of the gravid uterus, spontaneous rectification occurs in the progress of pregnancy. In very rare instances, however, of retroflexed uterus, as first suggested by Merriman, and as confirmed by the observations of Oldham and Stillé, pregnancy may go to term or near it, though the uterus remains retroflexed.

In some cases, again, spontaneous abortion is not an infrequent result. But should neither spontaneous nor artificial restoration be made, nor abortion occur, incarceration follows, for the unusual development of the uterus observed by Oldham and by Stillé is so rare an event that it may be omitted from consideration. When the uterus remains imprisoned, there will result retention of urine and obstruction of the rectum; uræmia and local or general peritonitis may occur; the bladder may rupture, or there may be a simple or a diphtheritic cystitis, and, as a consequence, detachment of the whole or of parts of the vesical mucous membrane. Valenta has reported a case in which retroflexion caused in the fifth month gangrene of the bladder, perforation into the small intestine, and death.

In making the diagnosis the bladder should be first emptied by the catheter if possible, but, if this be impossible, especially in case there be great accumulation of urine, by the aspirator; if the patient is very sensitive an anæsthetic must be employed. Given the probable fact of pregnancy, its certain proof may usually be had from auscultation in case the pregnancy has advanced to four months or more. Then by examination with the finger, both vaginal and rectal, by abdominal palpation, and finally by combining the latter with vaginal touch, the fact of retroversion or retroflexion of the uterus will in most cases be clearly established.

The diagnosis of the deviation having been made, the next step is to correct it, and prevent its return. Supposing the simplest form of the disorder, a displacement at two or three months being present, and the uterus be mobile, its correction can generally be readily made by the bimanual method, and the return of the disorder be prevented by the application of a suitable pessary, which in most cases ought to be worn until the end of the fourth month. Even if the uterus be almost, or quite immobile, and no grave consequences of the displacement be yet present, its gradual restoration may be possible. In attempting such restoration the patient takes the knee-chest position and then the operator introduces the large blade of a Sims's speculum, pressing the point of the blade as far up as possible in the posterior cul-de-sac. By this pressure upon the posterior wall of the uterus, we endeavor to lift up the organ while retracting the perineum; the movement of the uterus may be assisted by hooking a tenaculum into the vaginal cervix, which is thus drawn backward and downward. The operation may be repeated for a brief time each day, should no unfavorable symptoms arise; there may be very slight gain each time, but patient perseverance will, in many cases, be rewarded with complete success. If, however, symptoms of incarceration are manifested, immediate restoration must be attempted. In such cases an anæsthetic will usually be required, and therefore the knee-chest position cannot be taken while efforts at restoration are made. Indeed, such position would hinder rather than assist return of the organ to its normal place in some degrees of this displacement; for example, in case the fundus of the uterus has descended, so as to be near the vaginal outlet, and the cervix is directed above the pubic joint, the organ occupying a position corresponding nearly with the axis of the pelvic inlet, the cervix being highest, it is manifest that there would be, so far as the action of gravity and atmospheric pressure are concerned, force exerted which would increase rather than lessen the displacement. Under such circumstances it is better for the patient to be lying upon her side, or upon her back. The four fingers of one hand may be introduced into the vagina to press the organ up, or two fingers applied to the anterior surface of the neck, now its superior, to draw this part downward and backward, while two of the other hand are placed in the rectum and the body of the uterus is by them pushed upward and forward. It is doubtful if the colpeurynter, whether introduced into the vagina or into the rectum, is of much value.

If the organ cannot be restored to its normal position, and serious symptoms are present, the only resource is to empty it, that is, produce abortion; and in those cases in which it was impossible to reach the os, for the introduction of a sound, puncture of the uterus, thus evacuating the amniotic liquor, has been successfully employed.

Herniæ of the Uterus.—Herniæ of the gravid uterus are rare. In some instances protrusion of a part of the organ may take place in an umbilical hernia, or again there may be a ventral hernia, the integrity of the abdominal wall having been lost from the distention of a previous pregnancy, or from an injury, the separation usually being between the recti muscles. The conditions which have been mentioned rarely give rise to serious difficulty during pregnancy, or in labor; nevertheless in the latter, if a considerable eventration is present, the uterus thus being withdrawn from the assisting action of the abdominal muscles during the second stage, that stage will be tedious, and an instance of this kind I have known. The comfort of the patient during pregnancy will usually be promoted by a suitable bandage.

The only other forms of herniæ known are inguinal and crural. Eisenhart states that hernia of the gravid uterus is nearly as rare as that of the non-gravid, and the slight preponderance in number of the former is probably due to the fact that pregnancy directs attention to a condition that would be otherwise unnoticed. In some historical references this writer states that Nicolaus Pol (1531) reported the first case; Cæsarean section was performed, the mother surviving three days, but the child lived until it was a year and a half old. In 1610 Sennert operated on a case, the mother living twenty days, and the child until it was nine years and a half old. Saxtorph's and Ledesma's cases are next given, that of the latter occurring in 1840. Rektorisk reported a case in 1860; the Cæsarean operation was done, the mother died, but the child lived.

Inguinal hernia has been frequently observed with uterus bicornis or didelphys. In Winckel's case, reported by Eisenhart, the uterus was bicornis; the hernia, which involved the right horn, occurred suddenly in the fourth month of pregnancy. Scanzoni has reported a case of inguinal hernia in a patient who had two pregnancies in one year, one of these being ended by spontaneous and the other by artificial abortion.

In either crural or inguinal hernia, Winckel advises abortion; but if the fœtus be viable, the Cæsarean section should be done at the end of pregnancy, and after the operation the uterus is, if possible, to be restored to the abdominal cavity; but if this cannot be done it should be extirpated.

Structural Diseases of the Uterus.—Two only of these will be considered, benign and malignant growths. Fibroids, or myomatous tumors of the uterus are comparatively rarely observed in pregnancy, for such tumors cause a relative sterility; thus, while the average sterility of women is one in eight, that of those suffering from such neoplasms is one in three. These tumors usually increase in size and become softer in pregnancy, and after this a par-

tial atrophy is frequently observed, more especially in those which have a predominance of muscular tissue in their structure.

Stratz (*Zeitschrift für Geburtshülfe*) has recently reported the results of 11 cases of uterine myomata observed in pregnancy. In 4 spontaneous abortion occurred, and in 3 it was induced; twice the tumor and the uterus were removed, and twice also the tumor only was taken away, once by laparotomy, and once through the vagina, and in the two latter cases only were living children born at term; all the mothers recovered. On the other hand, of 13 women in whom the tumors were discovered during labor, 7 died, and 8 of the children were saved. Hence he draws the conclusion that intervention during pregnancy is much more favorable for the mother, while delay until labor occurs is more favorable for the child. Recognizing the fact that the mother's is more valuable than the child's life, Stratz holds that intervention during pregnancy ought to be the general rule; that in very many cases abortion should be produced, as the sole rational measure, since myomotomy is yet too recent an operation for its true value to be known. But it should be remembered that whether a fibroid is a serious complication of pregnancy depends upon its size and position; growths of moderate size, unless so situated that they notably lessen the size of the birth-canal or seriously interfere with the expansion of the lower segment of the uterus, may not prevent normal labor; and such growths, as the experience of most practitioners will testify, are those which are most frequently observed. If the fibroid is situated at the uterine fundus, abortion is very liable to occur. In many instances where the growth was in the lower part of the uterus or in the cervix, and submucous, it was successfully extirpated during labor. If the tumor be subserous, and not so large that it prevents the development of the uterus, there is no indication for interference; on the other hand, its removal is indicated if it be large, and then, in case it be pedunculated and without extensive adhesions, that removal is not difficult, nor likely to be followed by interruption of the pregnancy.

If the fundus of the uterus be affected by cancer or by sarcoma, pregnancy is not at all probable, and should it happen, abortion is inevitable. Malignant disease of the cervix, however, is not so invariable an obstacle to impregnation. Nevertheless, it is a comparatively rare occurrence that a woman who has cancer of the womb becomes pregnant; the statistics presented by Stratz, *op. cit.*, show that in 1,034 cases conception was observed in only 12.

Pregnancy causes the more rapid growth of malignant tumors of the uterus, and extirpation of the diseased structure, although the operation may cause abortion, is plainly indicated.

If an ovarian tumor is small it rarely interferes with pregnancy, and, therefore, the statement made by Stratz is too absolute, that the occurrence of pregnancy in a woman having such a growth is a sufficient indication for at once performing ovariotomy. But should the tumor, either by size or position, interfere with the progress of the pregnancy, ovariotomy is indicated, and the earlier in gestation the operation is done the more favorable the prognosis. In fourteen cases of ovarian tumors complicating pregnancy, reported by Stratz, ovariotomy was done; all the mothers recovered, and thirteen out of fifteen children were saved, abortion occurring in two cases, and there being one twin pregnancy. These results are very much better than those following the expectant plan, the induction of abortion, or puncturing the cyst.

Mastitis, ending in resolution or in suppuration, has occasionally been observed during pregnancy, but the treatment of this affection does not require special consideration. There is a normal hypertrophy of the mammæ in pregnancy; but in rare instances this hypertrophy becomes very great, transgressing all physiological bounds, and in such cases abortion is liable to occur; usually the hypertrophy is followed by atrophy when the pregnancy is over. Treatment—including the application of support to the enlarged breasts, of iodine, or of cold, and of compression, and the internal administration of the potassic iodide—has rarely proved of notable value.

Tumors of the breast, whether benign or malignant, usually increase rapidly in size during pregnancy; in a few instances malignant growths begin at this time. If mammary cancer is complicated by pregnancy, or originates during it, extirpation of the growth is indicated.

Diseases of the Ovum.—There will be included in this class anomalies of the amnion, the chorion, the deciduæ, and of the placenta and cord, diseases of the fœtus having been elsewhere considered in this work.

Amniotic Adhesions and Bands.—Adhesions between the amnion and the fœtus and amniotic bands are in some instances met with. These were supposed by some observers to result from inflammation of the amnion, amniotitis; but the hypothesis now most generally accepted is that adhesions are caused by an arrest of development, and that bands uniting the skin of the fœtus, or, in some instances, floating in the amniotic liquor, either unattached or attached only at one end, result from stretching the adhesions through an increase of

FIG. 3097.—Amniotic Adhesions and Bands. (Charpentier.)

the amniotic liquor. Deformities of the fœtus may be caused by these anomalies, and, in some instances, amputation of a limb, or part of it, may be effected by an amniotic band.

Polyhydramnios; Oligohydramnios.—By the former—commonly called hydramnios—is meant excess, and by the latter deficiency, of the amniotic liquor. Whenever the amniotic liquor is in marked excess of two quarts, there is said to be polyhydramnios; in some instances this excess is between twenty and thirty quarts. The affection is more frequent in multigravidæ than in primigravidæ—according to McClintock, 23 to 5; more frequent in twin than in single pregnancies, and generally in the former the twins are of the same sex; and in some cases there is polyhydramnios in one fœtal sac, oligohydramnios in the other; in a few instances polyhydramnios has been found in extra-uterine pregnancy.

The disease has been attributed to amniotis, to persistence of the vasa propria of Jungbluth, which usually become obliterated in the last months of pregnancy, to great activity of the renal function of the fœtus, to transudation of serum of the maternal blood through the fœtal membranes, and to transudation from the fœtal circulation.

Two forms of polyhydramnios are met with, the one chronic, the other acute; the former is much the more frequent. In the chronic affection the dropsical accumulation takes place slowly, and is, therefore, better tolerated; but in the acute disease the accumulation is very rapid, and fever is present. Tarnier distinguishes the last form of the affection as primary or secondary; by

the latter is meant an acute form grafted upon the chronic.

The most striking characteristics of polyhydramnios are the rapid increase in size of the uterus—the organ at five months, for example, being as large as it should be at the end of pregnancy—and the very distinct fluctuation. Besides these we have pressure-accidents relating to respiration and circulation, the former becoming difficult, so that the patient must be erect or sitting; and from interference with the latter there may be general œdema, but there always is œdematous swelling of the lower limbs; the uterine walls, both by abdominal and by vaginal examination, are found tense and resisting, and obstetric palpation and auscultation are difficult, or may even yield negative results so far as clearly establishing the diagnosis of pregnancy; vaginal examination shows the os high up, and a tense, elastic mass, in some cases giving distinct fluctuation, is found blocking up the pelvic inlet; the neck may be partially or completely effaced.

The induction of labor is clearly indicated if the uterine distention be so great that the life of the mother is in peril. The obstetrician must remember that there is great liability to post-partum hæmorrhage from uterine atony, and must guard against this accident.

Oligohydramnios may, according to some, cause adhesions between the fœtus and the amnion, and the subsequent formation of amniotic bands by stretching these adhesions when the amniotic liquor becomes abundant: a more probable explanation of these conditions has been given. But it seems not doubtful that in those cases in which this fluid is scanty, the fœtus cannot have its normal attitude, and undergoes injurious compression from which deformities may result.

Diseases of the Chorion.—Cystic Mole, or Hydatidiform Degeneration of the Chorial Villi. This is an affection of

Fig. 3098.—Cystic Mole. (Charpentier.)

the chorial villi, but whether these are primarily or secondarily involved has been a matter of dispute. Hecker asserted that it arose from failure in the development of the allantois, but this view, though strengthened by the absence of blood-vessels in the walls of the vesicles, is not generally accepted. Lesions of the decidua are present, and these in most cases follow the change in the villi; but sometimes, according to Virchow, endometritis precedes the chorial disease, and may contribute to it. The arguments in favor of the maternal origin of the disease are its frequent recurrence in the same woman—thus Depaul reported the case of one patient who thus suffered in three, and Mayer, one who had the disease in eleven pregnancies—and its occurrence in women advanced in years—for example, Schroeder saw it in one woman fifty years of age, and in another fifty-three years of age. On the other hand, instances of twin pregnancy, in which one ovum was diseased and the other healthy, have been observed, and such facts strongly indicate the fœtal origin of the malady.

The generally accepted view of the nature of this affection is that proposed by Virchow, who believes that it arises from a myxomatous degeneration of the chorial villi. The part affected by this change is converted into a vast number of cyst-like formations—there may be five or six thousand; these vary in size, some being as large as an almond, others as small as, or smaller than, a currant, and still others scarcely visible to the unaided eye. Depaul states that they vary in size from a pin's head to a pullet's egg; they have pedicles, but these are not attached to a common stem, as is seen in a bunch of white currants, or of grapes, to which their appearance has been compared, but to other vesicles. The semi-fluid substance in the vesicles is similar to that found in Wharton's jelly; it is composed of water, albumen, mucine, salts, chloride of sodium, and phosphoric acid (Fig. 3098).

If the disease begins before the formation of the placenta, the entire chorial tissue will be involved, but if after, the disease is limited to the placenta chiefly, and in some instances to a part of it.

The affection is rare, Madame Boivin having met with but one case in 20,375 deliveries.

Depaul has presented three important signs of a cystic mole: 1. A more rapid enlargement of the abdomen than is seen in normal pregnancy. In one of his patients the uterus was four fingers' breadth above the umbilicus at four months. 2. Attacks of uterine hæmorrhage. This symptom has occurred as early as the forty-fifth day, and, on the other hand, has been delayed as late as the fourteenth month. Discharges of blood in some cases alternate with discharges of a watery fluid. 3. The expulsion of separate vesicles, or of clusters; of course this sign is conclusive. The danger to the woman is exhaustion from repeated hæmorrhages, or a single hæmorrhage may be so great as to be fatal. The fœtus in almost all cases dies. Nevertheless, there are instances in which an "hydatid" mass has been expelled, and the pregnancy continued until term, when a healthy child was born. Such cases were probably examples of a twin pregnancy in which myxomatous degeneration affected one ovum, which was discharged, while the other remained healthy.

No active treatment is required until hæmorrhage occurs. If this be slight, rest, cold acid drinks, and an opiate may be sufficient. Even if the disease be proved by the expulsion of the so-called hydatids, it does not follow that the uterus is to be at once emptied. The dominant fact guiding the treatment is hæmorrhage. If this persists, if it is grave, and only temporarily restrained by the tampon, the os uteri should be dilated, the uterine cavity emptied, and hæmostasis secured by proper means.

Destructive Cystic Mole.—Zweifel describes, under the designation *Die destruirende Blasenmole,* rare cases, of which only three have been observed—one each by Volkmann, Waldeyer, and Kriger—in which the chorial villi grow so rapidly into the uterine wall that they reach the peritoneal covering, and hence this wall becomes greatly weakened. The difficulty in removing such a growth, the impossibility of making the removal complete, and the liability of causing rupture of the uterus, are obvious; but without such removal the hæmorrhage cannot be arrested. Two of the three cases that have been reported died from hæmorrhage, and the third from peritonitis. Where interference is necessary, Zweifel advises dilatation of the os by a compressed sponge that has been thoroughly disinfected by hot air; expression of the

uterine contents may be tried, and if this fails, the hand must be introduced into the uterus and the curette then employed, this operation being followed by washing out with antiseptic injections the parts detached.

Myxoma of the Membranes of the Ovum. In addition to the "partial hyperplasia of the fœtal connective tissue in the chorial villi, the cystic mole, Breslau and Eberth have found a similar hyperplasia in the parts of the chorion without villi. This appears in the form of a soft gelatinous thickening of the membranes, and during labor it feels like the scalp distended by serous infiltration" (Zweifel).

Fibrous Myxoma of the Placenta. This degeneration was first described by Virchow, who gave to it the name of fibrous myxoma of the placenta. The growth is composed of mucous and fibrous tissue; it is vascular, but there are no vesicles as in cystic degeneration of the chorial villi. In some cases there is a single large tumor, as in one reported by Storch, in which the mass was five inches and a half long, and three inches and a half broad; but in other instances there is a large number of small tumors.

Decidual Endometritis.—Four varieties of this affection have been described.

1. *Diffuse Decidual Endometritis.* This usually affects only the uterine decidua, decidua vera; there is thickening of the membrane from proliferation of the decidual cells, and development of the connective tissue; it is also asserted that the subjacent muscular fibres may undergo hyperplasia.

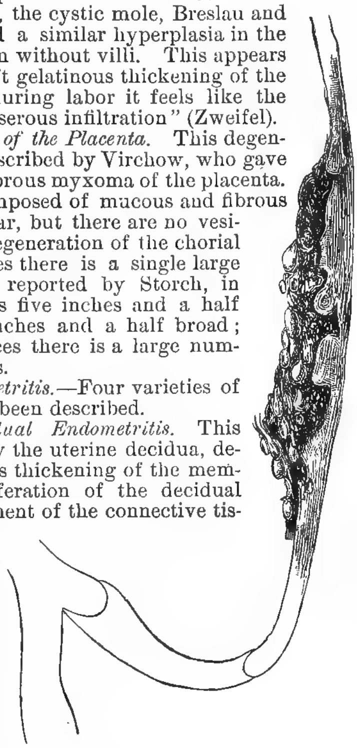

Fig. 3099.—Destructive Cystic Mole.

2. *Polypoid Decidual Endometritis.* This is characterized by thickening of the decidua vera, and polypoid growths, irregular in form, broad-based, and about three-fourths of an inch in height (Fig. 3100).

Breus states that if polypoid endometritis occurs early, the inflammatory process readily extends to the chorial villi, with consequent atrophy of the ovum and abortion; upon the aborted ovum there will be found the proofs of diffuse and polypoid decidual endometritis.

3. *Cystic Decidual Endometritis.* In this form of the disease not only the decidua vera is involved, but also the glands; obstruction of the gland-ducts results from inflammatory swelling, and cysts are formed—in other words, they are retention-cysts.

4. *Catarrhal Decidual Endometritis.* The characteristic evidence of this disease is the discharge from time to time of a watery fluid, known as hydrorrhœa gravidarum. This discharge, which may occur as early as the third month, but usually not until the late months, of pregnancy, is more frequently observed in multigravidæ than in primigravidæ; it is albuminous, generally yellowish, and may contain blood. Many of the cases of supposed rupture of the membranes and discharge of the amniotic liquor days and even weeks before labor, are really instances of hydrorrhœa, a discharge of so-called false waters occurring. Slight pains commonly accompany the discharge; in most cases it is repeated several times. Premature labor rarely follows hydrorrhœa, but its possible occurrence suggests that the patient, especially if there are uterine contractions, should lie down, and decided pain indicates the use of opium either by rectal injection or by the mouth. The causes of decidual endometritis are not well known. In some cases it is apparently the result of syphilis, and in others of violent bodily effort, or of excessive work; in others it existed prior to the pregnancy, and in still others follows the death of the fœtus.

Decidual Hæmorrhage.—Extravasation of blood may take place involving all the deciduous membranes; "if the extravasate is situated in the serotine membrane it may extend between the reflexa and the chorion, invaginating the latter and the amnion into the cavity of the ovum, and the embryo, if not previously dead, dies from compression;" sometimes even the cavity of the ovum is ruptured and the effusion penetrates into it. If the ovum is not ruptured the amniotic liquor is absorbed after the death of the embryo, and the latter disappears, the ovum containing only the remains of the cord. If expulsion of the ovum occurs soon after the hæmorrhage, the mass is composed chiefly of a large clot of blood, and has been called a blood mole. If, however, the expulsion be delayed, the embryo having prematurely escaped, or having undergone absorption, the effused blood has become more firm, and regressive metamorphoses having taken place, the mass is known as the fleshy mole. In either case the pregnancy has been called a false or molar pregnancy, and the mass expelled a blighted ovum (Fig. 3101).

Placental Apoplexy.—Jacquemin has described three forms of placental hæmorrhage. In the first the blood is infiltrated in one or several lobes of the placenta; in the second it occupies an irregular cavity which presents projections in different directions; but in the third there are regular and circumscribed cavities, varying in size from a hemp-seed to a pigeon's egg; these effusions are usually multiple, and at first appear as blood-red extravasates, but afterward lose their deep hue and become grayish-red, or yellowish-white, fibrin-like masses. According to Kleinwächter placentitis is the usual cause of these hæmorrhages.

When the effusions are multiple or large, they may so seriously interfere with the nutrition of the fœtus that its death results.

Placentitis.—According to Hegar and Maier, inflammation of the placenta may originate as a cell proliferation of the decidual tissue, or from the larger fœtal arteries; it soon terminates in induration; in some cases it results in strong adhesions between the placenta and the uterus, requiring at labor manual detachment of the former. The

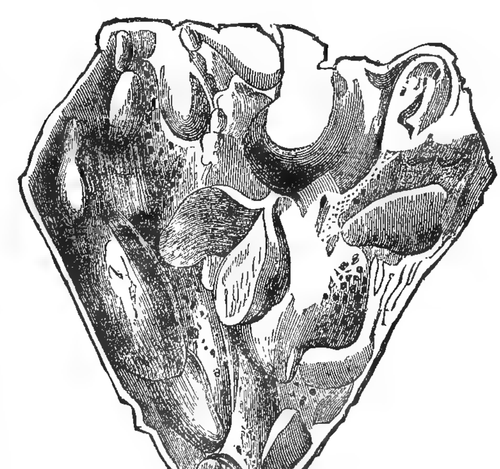

Fig. 3100.—Polypoid Decidual Endometritis. (Charpentier.)

formation of pus is, according to Zweifel, exceedingly rare, and can only be ascertained by the help of the microscope.

Calcareous and Fatty Degeneration of the Placenta.—The presence of sand-like grains either upon or in the maternal or the fœtal portion of the placenta is not uncommon; in some cases the calcareous products may present

the form of needles or of scales. The presence of these formations is without importance.

Fatty degeneration has been described by Barnes "as generally partial, invading one or more cotyledons, or part of them, forming in many cases diseased masses imbedded in comparatively healthy tissue, thus giving evidence that it originated during the life of the fœtus. In some instances we find, indeed, a living fœtus with a placenta in part affected; in others we find the disease more advanced and the fœtus dead, but with some healthy placenta, the vessels still containing blood. To the naked eye the fatty placenta may exhibit masses of a yellowish pale color, more solid than the spongy, healthy tissues surrounding them, and easily friable." Among the consequences of fatty degeneration is abortion. Barnes holds that this change may explain some cases of hæmorrhage during gestation which are attributed to placenta prævia.

Tumors of the Placenta.—Cystic and solid tumors of the placenta are sometimes met with; one variety of the latter has been previously mentioned. Klotz has recently (*Archiv für Gynäk.*, Band xxviii.) described adenoma of the placenta. This tumor originates in the spongy portion of the placenta or in the glandular cavities of the serotine decidua. Adenoma of the placenta causes the

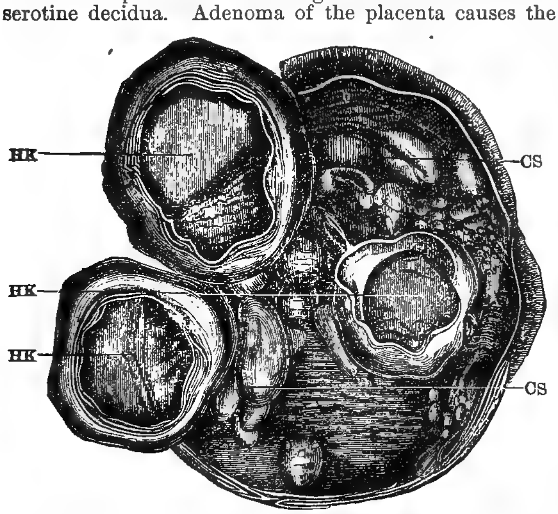

FIG. 3101.—Hæmorrhagic Mole. CS, blood-clots; HK, hæmorrhagic cysts. (Charpentier.)

death and the expulsion of the fœtus, and this is followed by retention of the placenta, the retention lasting for weeks, and even months.

Syphilis of the Placenta.—The following are the microscopical appearances of placentæ from syphilitic mothers, as given by Zilles in his valuable monograph, *Studien über Erkrankungen der Placenta und der Nabelschnur bedingt durch Syphilis* (1885): The placenta is of massive development and of great weight, in comparison with the imperfect development of the fœtus. The general color of the organ is pale red, but in the diseased portions yellowish-white. Here and there the tissue is firmer, more resistant, compact, and friable than the normal placenta. At various points gummatous nodules are found; they are wedge-shaped, nodulated, fibrous formations, with their bases in the decidua, but they generally grow smaller as they penetrate more deeply into the fœtal placenta; they vary in size, some being as small as a pin's head, others as large as a walnut; in some instances they occupy circumscribed portions of the entire thickness of the placenta. The gummata upon section show a structure of concentric lamellæ; the external layers are firmer, more like fibrous tissue, and have a grayish-yellow color, while in the centre there is a yellowish-red, or orange-yellow, cheese-like, soft or fluid material. Scattered through the peripheral zone are nodules of a cloudy orange-yellow color and cheesy in character, about the size of miliary tubercles. If complete degeneration of the central portion has occurred, an irregular cavity is present, its walls being formed of fatty, granular débris, and covered with pus-corpuscles. The decidua at the uterine surface is greatly thickened, cloudy, and presents yellowish-white spots. If the fœtus is affected, nodules, similar to those previously described, are found under the amnion. The umbilical cord is firmer than normal, and upon section a remarkable crescent-shaped thickening of the vessels can be seen with the naked eye. There are also seen the characteristic nodules in the tissue of the cord at some distance from the vessels.

Anomalies of the Cord.—Coils of the Cord about the Fœtus or its Members. One or more loops or "circulars" may be around the fœtus, or one of its members; the part most frequently thus encircled is the neck, and in one case that has been reported the cord was wound around the neck eight times. This accident occurs more frequently in multigravidæ than in primigravidæ, and is oftener found with the male than with the female fœtus. In general no injurious result follows such position of the cord, but in some cases the calibre of the umbilical vessels is materially lessened, and death of the fœtus ensues.

Knots.—Accumulation of Wharton's jelly at particular parts of the cord, causing there a notable projection, is known as a false knot. But a true knot is formed if the fœtus passes through a loop in the cord; such a knot is met with once in two hundred cases; the knot is in some cases double, and in others, instead of either one single knot or a double knot being present, there are several single knots. Depaul, for example, saw a case in which there were five. The knots are recent, or old; in the former, which occur during delivery, the diameter of the cord is normal, there is no lessening of Wharton's jelly; but in the latter the knot is smaller, Wharton's jelly being notably lessened. If the knots are contiguous, and are formed during pregnancy, it is possible, according to some authorities, that they may be drawn so tightly that the circulation is seriously interfered with and the fœtus dies; but ordinarily the circulation is not interrupted from this cause.

Torsions.—The umbilical cord normally presents torsions, this twisting being, in by far the larger number of cases, from left to right. But there may be an excessive number of these torsions; Dohrn saw a case in which there were 85, Meckel 95. They have been more frequently observed in the case of the male than in that of the female fœtus, the proportion being 8 to 5. Spiegelberg described them as præmortal, and postmortal; the first are usually caused by the movements of the fœtus, but the second by those of the mother. Dancing is mentioned by Kormann as a cause of twists in the cord. Torsions are most numerous near the umbilicus, and next in the vicinity of its placental attachment. In some instances division of the cord has followed torsions, the fœtus thus being left free in the uterine cavity; in rare cases occlusion of the vessels or great stenosis has been thus caused, and of course in either condition the fœtus dies.

Stenoses of the Umbilical Vessels.—Narrowing of the vessels of the cord may occur independently of knots or torsions. These stenoses, first observed by Oedmanson and Winckel, and described by Birch-Hirschfeld, are usually found in the vein near the placenta. The latter also found circumscribed stenoses of the arteries in the vicinity of the umbilicus, and also near the placenta; he regards them as resulting from syphilis. Spaeth states that atheromatous changes may occur in the arteries. Hyrtl found stenosis of the umbilical vein consequent upon periphlebitis. *Theophilus Parvin.*

PRESBYOPIA (Pr), from πρέσβυς, old, and ὤψ, eye, is "the condition in which, as the result of the increase of years, the range of accommodation is diminished, and the vision of near objects interfered with."[1] The range of accommodation diminishes year by year, from about 15 dioptrics ($1/2\frac{2}{3}$), at the earliest age (ten years) at which accurate observations have been made, to about 1 dioptric ($\frac{1}{40}$), at the age of sixty-five or seventy; at forty it amounts to something less than 5 dioptrics ($\frac{1}{8}$), and at forty-five to about 3.3 dioptrics ($\frac{1}{12}$).[2]

Of the 15 dioptrics of accommodation which the child

of ten years can bring into exercise, from two-thirds to three-fourths (10 to 11 dioptrics) may be lost without greatly incommoding an emmetrope in ordinary near vision. In emmetropia the distance (P_2) of the binocular near-point (p_2) is the reciprocal of the number of dioptrics of accommodation; hence, with a binocular range of accommodation of 5 dioptrics, $P_2 = \frac{1}{5}$ metre (20 centimetres = 8 inches), at which distance the smallest print in ordinary use is easily deciphered by eyes of average visual acuteness; when the range of accommodation is reduced to 4 dioptrics $P_2 = \frac{1}{4}$ metre (25 centimetres = 10 inches), at which distance ordinary newspaper print is still easily read; with the loss of another dioptric of accommodation (leaving but 3 dioptrics available), $P_2 = \frac{1}{3}$ metre (33.3 centimetres = 13.12 inches), and the reading of fine print becomes difficult, except under the favorable conditions of good illumination and normal acuteness of vision. These several values of P_2 correspond, in emmetropia, to ages ranging from about thirty-eight to about forty-seven years, and few emmetropes attain the latter age without seeking aid from convex glasses in reading or other fine work; the adoption of convex glasses by an emmetrope under forty, is generally determined either by the exacting nature of the work in which he habitually employs his eyes, or by the fact that his acuteness of vision is somewhat below the normal standard. When at the age of from fifty to fifty-five years the range of accommodation is reduced to 2 dioptrics, $P_2 = \frac{1}{2}$ metre (50 centimetres = 19.68 inches), and the book must be held at arm's length, at which distance only exceptionally large print can be read; but, even with this range of accommodation, a public speaker may be able to read fluently from a plainly written manuscript lying before him upon a reading-desk or table.

The diminution of the range of accommodation with advancing years is a strictly physiological change, and is directly related to the progressive increase in the hardness of the crystalline lens, in consequence of which it becomes less and less capable of undergoing the change in curvature required for the adjustment of the eye for near vision. As this hardening of the crystalline occurs in all eyes alike, irrespective of their refractive condition, as determined by the relation of the curvature of the refractive surfaces to the length of the axis of the eyeball, it would be scientifically correct to define presbyopia as the loss of accommodative power incident to advancing years. Immemorial usage has, however, associated the name with the special condition in which, as a result of increasing age, near vision becomes indistinct while distant vision remains either absolutely or relatively unimpaired. As thus defined, presbyopia is an incident in the life-history of all emmetropes and hypermetropes, and also of myopes whenever the myopia is of low grade—say, 3 dioptrics or less. In myopia of higher grades, say, of 4 dioptrics or more, the distance of the far-point remains within $\frac{1}{4}$ metre (25 centimetres = 10 inches) of the eyes, which is somewhat less than the usual reading distance for fine print; so that the characteristic disability of presbyopia, namely, the failure of vision for small near objects, is either never developed or only very late in life.* The apparent antagonism between myopia, in which only near objects are seen distinctly, and presbyopia, in which distant objects are seen clearly, while near objects appear confused, was very early recognized,[3] and, in the absence of any clear conception of the nature of the function of accommodation, presbyopia was, for more than two thousand years, regarded as the opposite condition to myopia. Hypermetropia, the true opposite of myopia, remained confounded with presbyopia until the middle of the present century, when the demonstration of the change in the form of the crystalline lens in accommodation by Cramer[4] and by Helmholtz,[5] and the masterly analysis of the phenomena of accommodation in its relation to the several anomalies of refraction, by Donders,[6] dispelled the cloud of obscurity in which the whole subject had been so long enveloped, and through which only momentary glimpses of the truth had been previously enjoyed by a few exceptionally acute observers.[7]

Premonitory signs of presbyopia may ordinarily be detected in emmetropes before the thirty-fifth year; exceptionally fine print, such as No. 1 of Jaeger's scale, is no longer read with the same perfect fluency as in youth, especially if the illumination is defective. Within the next five years the finer newspaper print loses something in sharpness of definition, and the finest needle-work becomes difficult, and perhaps deteriorates somewhat in quality. If the acuteness of vision (V—see Optometry) is normal, and the print is not too fine, relief from the consciously increasing effort in accommodation may be obtained by holding the book or work a little farther from the eyes; but if vision is subnormal, or if the print is bad or very fine, a stronger illumination may be demanded without increasing the reading distance. By the age of forty-five the disability has generally increased to the point that only fairly large print can be read with ease by ordinary artificial light, and a more powerful lamp is procured, or the book is held nearer to the light; about this time the probable need of help from glasses commonly suggests itself, and they are, perhaps, tried and adopted.

A hypermetrope habitually wearing neutralizing (convex) glasses, or a myope wearing neutralizing (concave) glasses, experiences the disabilities of presbyopic vision at about the same age, and in about the same degree, as the emmetrope; thus, between the ages of forty and forty-five, the hypermetrope discovers that his convex glasses are no longer quite sufficient in reading, and similarly, the myope discovers that his concave glasses have become something of a hinderance in near vision, although, in both cases, the neutralizing (convex or concave) glasses continue to serve perfectly for distant vision. A change to stronger convex glasses by the hypermetrope, or to weaker concave glasses (or, perhaps, the temporary removal of his glasses) by the myope is the remedy which now suggests itself, and which is, sooner or later, adopted. With the change of glasses reading again becomes easy, but with a corresponding falling off in the distinctness of distant vision; for this reason, an elderly ametrope ordinarily requires two pairs of glasses, the one pair (neutralizing) for distance, the other pair (stronger convex or weaker concave) for reading and other near work.

A hypermetrope, not wearing convex glasses, experiences the disabilities of presbyopia at an earlier age than the emmetrope, after having, perhaps, passed through a more or less protracted stage of suffering from asthenopia (see Asthenopia). In myopia, on the other hand, if of low grade, the reading-power with the unaided eyes is retained to a more advanced age than in emmetropia; in the higher grades of myopia the reading-power is retained indefinitely.

As a result of the very gradual increase in the resistance which must be overcome in order to effect such degree of accommodative adjustment as is still possible in presbyopia, the relation of the accommodation to the convergence undergoes an important change, the binocular accommodation (A_2) associated with convergence for the habitual reading distance of from thirty to thirty-five centimetres (12 to 14 inches) becoming at length nearly equal to the absolute accommodation (A); in other words, the binocular near-point (p_2) comes to coincide very nearly with the absolute near-point (p). With the use of convex glasses in near work, the distance (P_2) of the binocular near-point (p_2) undergoes a rapid increase, so that such reading-power as may have been retained up to the time of the adoption of the glasses is speedily lost, and reading without glasses becomes inpossible. Hence the common experience of presbyopes, that having once formed the habit of using convex glasses, their continued use has become imperative, and this whether the glasses have been adopted somewhat prematurely, or only after the need of them has become urgent. The too early use of convex glasses is, therefore, to be deprecated, as entailing upon the wearer all the disabilities of presbyopia several years, perhaps, before the normal age; on the other hand,

* That is, in connection with the moderate falling off of the refraction which occurs late in life, see p. 24.

as there is a definite limit to the absolute range of accommodation at any given age, the use of convex glasses cannot, as a rule, be deferred by an emmetrope much beyond forty-five, unless he be content to forego the use of the eyes in reading ordinary print, or in other fine work.

The total disuse of the accommodation for a considerable period, especially if occasioned by protracted and exhausting illness, may lead to the premature development of presbyopic symptoms, which may then be interpreted as an indication for the immediate adoption of convex glasses. If glasses are used in such a case, they should be of the least power compatible with the use of the eyes under favorable conditions of illumination, and the patient should be encouraged in the hope that, as the accommodative power increases with use, the glasses may be laid aside. In cases of this kind it is often possible to bring the accommodation again into effective use by the instillation, once or twice daily for a few weeks, of a weak solution of pilocarpine, and thus to put off the use of glasses for perhaps several years.

In addition to the impairment of the accommodation, which is the essential characteristic of presbyopia, the refraction undergoes, in the course of time, a slight but positive diminution, so that ultimately an emmetrope becomes slightly hypermetropic (H *acquisita*—see Hypermetropia), a hypermetrope somewhat more hypermetropic, and a myope somewhat less myopic; a very low grade of myopia may thus give place to emmetropia, or may even pass through emmetropia to hypermetropia. A low grade of hypermetropia which, sooner or later, necessarily becomes absolute (H *absoluta*), is, in fact, the ultimate normal condition of all emmetropes, so that weak convex glasses come to be required for perfect vision at a distance; hypermetropes similarly require a moderate increase in the power of their convex glasses and myopes require a corresponding diminution in the power of their concave glasses. This falling off in the refraction is ordinarily scarcely to be detected at the age of forty-five; at sixty it may amount to perhaps 0.5 dioptric, at seventy or seventy-five to 1 dioptric, and at eighty to 2 dioptrics or more.[8]

The treatment of presbyopia is necessarily confined to the palliation of the actual disability, by the use of such convex glasses as may suffice to supplement the failing accommodation and also to correct any existing hypermetropia, whether original or acquired. A person originally emmetropic may, at the age of seventy, require convex glasses of as much as 5 dioptrics power ($\frac{1}{8}$), in order to read fairly good print at a distance of from ten to twelve inches; and if the acuteness of vision is somewhat below the normal, it may be necessary to use glasses of 6 or 7, or even 8 dioptrics ($\frac{1}{7}$ to $\frac{1}{5}$), in order to admit of reading at the shorter distance of from nine to seven inches. In the case of a person originally hypermetropic, the measure of the required glasses will be increased by a quantity equal to the grade of the hypermetropia; in myopia the measure of the glasses will be similarly diminished.

The glasses first given to a presbyopic emmetrope of from forty to forty-five years of age, should ordinarily not much exceed 1 dioptric (say $\frac{1}{40}$ or $\frac{1}{36}$), and, in many cases still weaker glasses (say $\frac{1}{60}$ or $\frac{1}{48}$) are quite sufficient, and may be more acceptable to the patient than stronger glasses. These glasses should be used for only such work as is performed with difficulty without glasses (reading fine print by artificial light, etc.), in order that the habit of using the accommodation may not be needlessly or prematurely abandoned,* and they should not be exchanged for stronger glasses so long as they continue to afford the needed assistance. Subsequent changes should always be made with reference to the glasses actually in use, adding perhaps 0.25 or at most 0.5 dioptric at each change, and it is generally advisable to retain the old glasses for a time, for reading in bright daylight, reserving the stronger glasses for more exacting work. It follows that a presbyope should always know the power of the glasses which he is using, in order that, in replacing a lost pair, he may not be reduced to the necessity of selecting new glasses at random, or after a hasty and inadequate trial, conducted, perhaps, by an "optician" whose knowledge is limited to the trick of selling his wares.

A presbyope using glasses suited to his condition, is able to use his eyes in near work freely and without fatigue; glasses of insufficient strength fall short of affording the full measure of relief, and glasses of excessive strength compel the holding of the book too near the face, thus imposing needless work upon the recti-interni muscles, and so possibly giving rise to muscular asthenopia * (see Asthenopia).

The clinical investigation of any case of presbyopia involves, first of all, the careful testing of the eyes for ametropia (hypermetropia, myopia, or astigmatism; see these titles; see also Optometry). As has been already explained, the measure of any hypermetropia that may be detected must be added to, and the measure of any myopia subtracted from, the value of the glasses ordinarily required by an emmetrope of corresponding age, in order to arrive at an approximation to the glasses to be given for reading. These tests are best conducted at a range of at least five metres (about sixteen feet), and only after the satisfactory determination of the state of the refraction, should a trial of reading-glasses, based upon this determination, be made. The final tests are made in reading fine print (such as Nos. 1 to 5 of Jaeger's test-types). If astigmatism is present, it should, as a rule, be accurately corrected by having one surface of each glass ground to the appropriate cylindrical curvature (see Astigmatism).

A rapid increase in the grade of presbyopia, necessitating frequent and considerable additions to the strength of the reading-glasses, should always be regarded as a suspicious symptom, indicating the possible development of glaucoma.

Repeated changes from weaker to stronger glasses, but with a shortening of the reading distance after each change, point to a falling off in the acuteness of vision, oftenest from failure in the perceptive power of the retina, or of the conductive power of the optic nerve.

A marked diminution in the apparent grade of presbyopia is occasionally observed rather late in life, and is due to the development of a myopic state of the refraction; this change, which is popularly known as "second sight," is ordinarily a symptom of incipient cataract.

PRESCRIPTION-WRITING. A medical prescription is a written order to the pharmacist to take certain quantities of certain medicines, deal with them in certain pharmaceutical ways, "put up" the product in certain form for dispensing, and label the package with certain directions for use. Correctness in prescribing, therefore, relates to the three several matters of the *selection of the ingredients* or *composition* of the prescription, the *fixing of quantities* or *computation* of the prescription, and the

* The proposal to make use of weak convex glasses somewhat before the appearance of marked presbyopic symptoms, for the alleged purpose of preserving and strengthening the sight, is so irrational as to justify the suspicion that it may have originated in the interest of trade; the only apparent foundation for such a practice is the fact that in hypermetropia convex glasses are needed at an earlier age than in emmetropia.

* Inasmuch as presbyopia is essentially an affection of the accommodation, the proposal to give convex glasses in which the spherical surfaces are ground upon prisms, with bases turned toward the nose (Scheffler[9]) is irrational. Such glasses, by lessening the tension on the convergence, tend also to lessen the concomitant exercise of the accommodation, and so may help to make stronger glasses acceptable than would otherwise be the case; this implies, however, the needless disuse of the remaining accommodation, and the promotion of an abnormally rapid development of the presbyopia.

actual *writing of the order* in technical style, or *expression* of the prescription, These several topics will be considered seriatim, in the order named.

I. The Composing of a Prescription.—Assuming that a prescription is intended, as should always be the case, to fulfil a single therapeutic purpose only, then the first point that presents is whether, under the circumstances of the case, a *single* medicine of the appropriate kind should be prescribed, or a *team* of such medicines. As regards this point, no general rule can be laid down —the matter will depend partly upon the nature of the therapeutic indication, and partly upon the respective peculiarities of the individual drug and the individual case. Thus to provoke *emesis*, a single drug is commonly prescribed; to excite *diuresis*, a team; while for *purging* the medicine will be single, if it be castor- or croton-oil, but multiple, if the selection be from among the resinous cathartics. The advantage of a team of similar medicines in prescription may be, on the one hand, a more *effective*, or, on the other, a more *kindly* accomplishment of the specific purpose in view, or it may be both possibilities combined. Thus, by a wise association in prescription of allied drugs, a maximum of therapeutic effect is attainable with a minimum of by-derangement. Having fixed upon the active member, or team of members, of the prescription, the next point is whether the medicinal working of the same may not be made even more effective or more kindly than would otherwise be the case by the further addition to the prescription of some special substance. Such increase in both lines—effectiveness and kindliness—may result by a chemical action upon the drug, on the one hand, or by a medicinal impression upon the system of the subject, on the other. Thus, as an instance of the working of a chemical action, stands the fact that the efficacy and kindliness of operation of a dose of *salicylic acid* are both enhanced by the addition to the acid of a solution of a sodic carbonate, whereby the salicylic acid, which under its own form is both insoluble and irritant, becomes the more soluble, and at the same time far less harsh, body, sodic salicylate. As instances of an associated medicinal impression by an unrelated drug affecting the operation of the active member of a prescription, may be cited the rather mysterious enhancement of the diuretic action of digitalis by the associate action of calomel, and the neutralizing of the griping of the rougher cathartics by the associated antispasmodic action of the pungent volatile oils, or of neurotics, such as belladonna or hyoscyamus. In the category of additions to a prescription for the purpose of enhancing *kindliness* of operation, belong *flavoring* substances. For an agreeable, or, at least, a not offensive potion, is not merely *pleasanter* than an ill-tasting one to swallow, but is also, by the very reason of non-offensiveness, far less likely than a nauseous dose to destroy appetite or derange digestion. The art of prescribing pleasant mixtures is therefore one of genuine advantage to the patient, as well as to the prescriber! Agreeability of taste is, of course, far more important in the case of fluid than of solid mixtures, and is attained, in the case of fluids, in part by wisdom in the selection of the active member of the prescription, and in part by the addition to the prescription of *sugar*, or of *syrup*, or of preparations of the more pleasantly flavored *aromatics*. Lastly, in composing a prescription, comes the thought of a possibly necessary substance to give *volume*, or, in the case of a powder or pill, to give *form*, or, in the case of a fluid mixture, to serve as a diluent, or as a solvent. The character and relative proportion of such a member of a prescription will vary so greatly in different cases, that no general rule affecting the selection of vehicles can be formulated. Members of a prescription for the several purposes named, are commonly referred to as, respectively, the *basis*, the *adjuvant*, the *corrigent*, and the *excipient*, or *vehicle*, of the prescription. In the association of different substances in a prescription, no matter what the purpose of the several ingredients, regard must always be had for the mutual *chemical* relations of the things so brought into mutual contact, lest undesirable reactions take place in the compounding (see Incompatibility, Medicinal).

II. The Computing of Amounts in Prescriptions. —The first point in the matter of amounts in prescriptions is, in general, *not to order more of the medicine than present prognosis seems to call for*. Not unnaturally, the laity instinctively argue that the remedy should fit the case in *measure* as well as in *mode*, and hence, that an excess of medicine in the prescription is *prima facie* evidence of a deficiency of skill on the part of the prescriber. They, furthermore, naturally object to the *paying* for the superfluous. Apart from these considerations, there are also many and obvious objections to a course that leaves half-used parcels of medicine to accumulate in a house, at the risk of inappropriate application on subsequent occasions, at ignorant hands. Hence, in cases where an exact forecast of the amount of a medicine likely to be required is impossible, it is wiser to order no more than will surely be within bounds, letting the prescription be renewed if the amount prove too little. Assuming due regard to be paid to this principle, then the determination of amounts in a given prescription proceeds, by theory, thus: the amount of *basis* will be the product of the two factors, *quantity of dose* and *number of doses* required, and the several amounts of the other ingredients will be deduced from the amount of the basis, in accordance with the respective requirements of relative proportion. In putting this theory into practice, however, the important consideration has to be regarded, that quantities must be such as can be conveniently expressed in terms of the system of weight or of measure employed in the prescribing. This consideration determines, in general, the use of *round numbers*, and, in particular, of *such* round numbers as best conform to the relation between denominations in the particular system of weight or of measure followed in the prescription. For example, in general, no prescriber would fix a dose to be expressed by such a number as *one and one-tenth*, whether referring to grains or grammes, nor would he ever estimate upon an aggregate of such an awkward number of doses as *seven*, or *eleven*, or *nineteen*, or *twenty-three*. And, for example again, in particular, the prescriber by the *apothecaries'* system of weight or of measure, recognizing the generally *duodecimal* ratio of the denominations of these scales, instinctively proportions the numbers of his prescription on a *duodecimal* basis. His ratios, that is, are as one to some one of the numbers 2, 4, 6, 8, 12, 18, 24, 60, 120, 180, 240, 480. On the other hand, if the *metric* system be the system followed, the *decimal* basis of this system almost of necessity entails the use of decimal ratios in proportioning amounts in prescription. Quantities are in this case fixed upon that are to each other as one to some number of this series of numbers: 2, 5, 10, 20, 25, 50, 75, 100, 200, 250, 500, 1,000. This fundamental difference in the figures to be used in working by the metric, as compared with the apothecaries', system, is a point very commonly overlooked by novices, in this country, in the art of prescribing by metric denominations. Because already fixed in the duodecimal habit through previous practice with the apothecaries' system, such novices are apt to compute in *duodecimal* ratios quantities which they then set down in terms of *decimally* related denominations—a proceeding wherein theoretical stupidity begets, as it should, practical disaster. For, by this proceeding, as it is hardly necessary to point out, there is wholly missed the one point of advantage which the metric system has to offer, namely, ease of computation by *decimal ratios*. A medicine, then, whose dose in prescription by apothecaries' weight is taken at *one grain*, is—or should be—in prescribing by metric weight, taken at *five* centigrammes, and not at the *six* centigramme amount which the American metric prescriber, translating from terms of apothecaries' weight, so commonly figures by. As well might an original metrician—to coin a convenient word—who essays a prescription by the apothecaries' system, first fix his dose, by his old metric habit, at five centigrammes, and then, blindly insisting on exactly that quantum, despite its unsuitableness to the foreign system of weights, prescribe in grains on the absurd basis of a *seven-eighths grain* dose!

Such are the essential points of the theory of computing prescription-amounts, and having due regard to these points, the prescription of *solid* mixtures for make-up into pills, powders, troches, suppositories, etc., is easy enough; but in the prescription of *fluid* mixtures many additional considerations enter into relation, as follows: In the first place, although it is not essential, it is yet elegant, and hence customary, to have a prescribed mixture aggregate *just a bottleful* of some one of the sizes of the medicine-phials of the shops. Regard must therefore be had to the several sizes of such bottles. In the United States medicine-phials are made of capacities conforming to *apothecaries' measure*, which capacities are severally as follows: *one, two,* and *four fluidrachms*, and *one, two, four, six, eight,* and *twelve fluidounces*. This fact of the conformity of medicine-bottles to apothecaries' measure, makes, in this country, the prescribing of fluid mixtures readier by the apothecaries' than by the metric system. Phials for metric prescription should be of the natural metric capacities, severally, of *twenty-five, fifty, one hundred, two hundred,* etc., *cubic centimetres;* but in this country phials of such capacities are, at least, not common. A few years ago an order, by this writer, upon a dealer for a set of such bottles, if they were procurable in the city of New York, was returned with the report that there was nothing of the kind in the market.

The second special point affecting amounts in the case of fluid mixtures relates to the case of solids in solution, the point being the physical fact that, in dissolving, a solid of a given measure in its condition of dry powder *does not augment the volume of the solvent by the full amount of such measure*, but, on the contrary, increases such volume so little that, in the ordinarily comparatively weak solutions used as medicines, the increment can safely be disregarded in the estimation of amounts for prescription.

The third point relates to the system by which, in a given case of a fluid mixture for internal giving, the *individual doses are to be measured out*. This consideration does not obtain in the case of solids, since, in such case, doses are defined by a stated number of pills, powders, or troches—are, that is, already apportioned by the apothecary. But in the case of a fluid mixture, the medicine is necessarily dispensed in bulk (except when put up in capsules), and doses must be measured out by the administrator at the bedside. The point then presents itself of practical bearing, whether, in a given case, the dose is to be measured by a method of precision—by use of a graduated pipette, if the dose be quite small, or of a graduated vessel if of ordinary or large dimension—or whether the determination is to be by the conventional *drop* on the one hand, or *spoonful* on the other. If a graduate is to be used, then the point now in question does not present itself; but if the *drop* or the *spoonful* is to measure the dose, then the consideration arises, in the apportioning of amounts in prescription, of the respective actual *dimensions* of these variable measures, under the conditions obtaining in the individual case. As regards the *drop*, it must be remembered that this measure varies in dimension, not only according to the viscosity and specific gravity of the fluid dropped, but also according to the *shape, extent,* and *character* of the surface from which the drop delivers itself, and even, furthermore, in the case of drops delivered from a phial, according to the *degree of fulness of the bottle* on the occasion of the dropping. A bottle with a flanged mouth, such as the ordinary medicine-phial, yields, with the same fluid, a comparatively large drop when full or nearly so at the dropping, and a comparatively small one when at least half empty, the difference in the respective drop-dimensions in the two instances being even as considerable as that between the numbers five and three. The reason for this difference in size of drops is that, from a full bottle, the contents begin to run out when the bottle is but slightly tipped, and so, because of the position of the free edge of the lip, the nascent drop creeps into the re-entrant angle formed by the under surface of the lip and the side of the neck, and there has a chance to grow to a comparatively goodly size before gravity determines the fall. On the other hand, a phial half empty must be tipped to the horizontal before the contents can run out, in which position the narrow rim of the lip points directly downward, and so presents but a small surface-area for the fluid to cling to. Under these circumstances the fall will necessarily be in comparatively small drops. As regards the *spoonful*, it must be remembered that this measure, like the drop, is subject to variation, so that, in the case of prescriptions containing powerful medicines, amounts should be calculated on the basis of the *maximum capacity of the measure.* Whatever, then, may be the variation from the calculated dose in actual mensuration, will be on the safe side of a *shortage* instead of a possible *excess* of amount. Now a given spoon will naturally hold more of a *viscid* than of a *thin* fluid, and, in practical mensuration, will more readily hold its full complement when the fluid is poured *into* it, as from a bottle, than when the spoon is made to dip up the fluid from an open vessel. Hence, in the case of a *syrupy* mixture, with the dose to be taken *direct from the phial*, the conditions obtain where the spoonful will be at its maximum; while, on the other hand, in the instance of a thin watery dilution standing in a tumbler, with the dose to be dipped up by means of the spoon, the measure, although the same in name, may be very different indeed in fact. Another point, which should be thoroughly understood, relates to the size of the average spoon of to-day as compared with the spoon of the same denomination of two generations ago. Coming down from our ancestors is the estimate of the *tablespoonful* as the measure of half a fluidounce, or sixteen cubic centimetres, and of the *teaspoonful* as that of a fluidrachm, or four cubic centimetres. These alleged equivalences, true of the average of spoonfuls of former days, are still handed down as present truth from teacher to student, and so come to be almost universally applied in prescription calculations. If, however, the reader will take from any chance pantry a sample of the average commoner kind of teaspoon, such as is generally relegated for service in the nursery, and will provide for himself an accurate graduate and a phial of water, he can learn for himself, in two minutes, the fact that the teaspoonful will run much nearer *six* to the fluidounce than the traditional *eight*—will equal the quantity of *five* rather than of *four* cubic centimetres. And, by the same token, the average tablespoonful of our own present spoons is of the dimension of *three* rather than of *four* to the two-fluidounce measure—of *twenty* rather than of *sixteen* cubic centimetres. And, indeed, in the case of thick fluids, such as strongly syrupy mixtures, or a fixed oil like castor-oil, where also the fluid is poured into the spoon, the spoonful will considerably exceed even these larger estimates. In view of these facts, this writer, in his teaching, has always advised for prescription-purposes the estimate of the equivalence of the teaspoonful as at five cubic centimetres, or at the rate of six to the fluidounce; and of the tablespoonful at twenty cubic centimetres, or at the rate of three to two fluidounces—six to four fluidounces.

By basing calculations on such assumed equivalences, any error in actual mensuration will be, as it should be, in the direction of a measure smaller rather than greater than intended. Furthermore, it is a happy fact that these equivalences give numerical relations far handier for purposes of calculation than the older estimates. In the case of the metric values, it goes without saying that for computation in decimal denominations, the numbers *five* and *twenty* are much more convenient for expressions of respective unit-quantities than the numbers *four* and *sixteen.* And in the apothecaries' system the proportion of six to the fluidounce permits of a greater number of easily calculated combinations than the time-honored eight to the same measure, as is shown in the tables below.

A fourth consideration affecting the estimation of amounts in the prescription of fluid mixtures, obtains in the prescribing of a solid to be borne in solution in an inert fluid menstruum, the point being the matter of the proper proportion between solid and solvent. Of course, in the first place, the proportion must be compatible with the solubility, in the selected menstruum, of the given solid; and, also of course, in the second place, if the

dose is to be extemporaneously diluted for the taking, the concentration of the prescribed solution may be to any degree so compatible with solubility. If, however, as so often is the case, the prescription proposes a solution fit for direct administration without further dilution, then the consideration of *taste* enters into relation. An over-strong solution will be rough to the taste, and may also be irritant or even corrosive to the alimentary mucous membranes; while, on the other hand, if the solution be inordinately weak, the volume required for the carrying of a proper dose of the dissolved basis may be inconveniently large. Of course, in this matter the individual peculiarities of the constituents of a given prescription will require individual consideration; but, in a general way, the truth obtains that the *teaspoonful* is best made the carrier of not more than—in convenient round numbers of the respective systems of weight—*twenty-five centigrammes*, or *five grains*; and, similarly, the *tablespoonful* of not more than, respectively, *one gramme*, or *twenty grains*, of a solid in solution. In the case of fairly bland substances, whose solubilities will at the same time permit, twice these quantities may be permissible; but such proportion should not be exceeded.

From this presentation of points affecting the prescription of fluid mixtures, it appears that, in cases where it is expected that the whole bottleful is to be used, the estimate of amounts must harmonize a trio of conditions as follows: 1, The total must be just a bottleful; 2, it must aggregate *about* the number of doses therapeutically indicated; and, 3, at the same time the amount of the active basis, while being such as to yield the proper strength of solution, must also be such as to admit of ready expression in terms of the system of weight or measure employed in the writing. In the use of the metric system this triple harmonization presents no difficulties, for the simple reason that since *any* amount is equally easy of expression by this system, it is only necessary to harmonize the first two considerations, letting the amount of active basis required foot up to what it will. Thus, for instance, let it be supposed that an indication seems to call for a medication three times a day for a few days; then all it is necessary to remember is that, if the active basis be one of small dose such that a teaspoonful is the more convenient carrier, a *fifty cubic centimetre* aggregate will fulfil the conditions of an even bottleful on the one hand, and about the requisite number of doses upon the other (ten teaspoonfuls, reckoning the teaspoonful at five cubic centimetres). Then the individual dose of basis may be taken unconditionally by the therapeutic indication—it may be fixed at one, two, three, four, five, six, seven, eight, nine, ten, or any odd number of centigrammes, and the expression of the aggregate will be equally easy, such aggregate being simply ten times the quantity for the individual dose, respectively as follows: 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, 0.80, 0.90, 1.00 Gm., etc. Similarly, if the case be one where a *tablespoonful* will be the more convenient measure for the dose, then a *two hundred* cubic centimetre volume will again yield ten doses (about the number indicated) of the selected dimension, and once more the individual dose of basis may be what it please, and the aggregate will be equally easy of expression. When, however, the *apothecaries'* system is followed in the prescription, at once a complication arises, for the reason that in apothecaries' weight all amounts are *not* equally easy of expression—some, indeed, being so awkward to express as to be practically unavailable. Thus, for instance, although by this system, as already pointed out, ratios are naturally taken in duodecimals, yet such a natural duodecimal multiple as *seventy-two*, representing grains, is a monstrosity for expression. In computing, therefore, by apothecaries' weight and measure, the prescriber is bound by the clumsiness of the denomination-ratios of the system, and so, for cases where the total basis exceeds a drachm, finds available for the fulfilment of the tripartite conditioning set forth above, a certain set of combinations only. These combinations the young prescriber must learn by rote. They are easily enough figured out for one's self; but for convenience of reference there are set forth, in tabular form below, the combinations convenient when the individual dose of basis is to be one or other of the several amounts, *five*, *ten*, *fifteen*, or *twenty* grains. If the individual dose of basis be *less* than a grain or two, then the total amount of basis required, being but a *moderate number of grains*, is easy enough of expression, and the difficulty now under consideration does not obtain.

TABLE OF CONVENIENT COMBINATIONS FOR THE PRESCRIPTION OF FLUID MIXTURES BY APOTHECARIES' MEASURE AND WEIGHT.

1. *Dose to be borne in an average teaspoonful, reckoning six teaspoonfuls to the fluidounce.*

Capacity of phial in fluidounces.	Number of teaspoonfuls contained.	Amount of basis to be prescribed in order to yield to the teaspoonful the several doses of			
		Five grains.	Ten grains.	Fifteen grains.	Twenty grains.
½	3	gr. xv.	ʒ ss.	....	ʒ j.
1	6	ʒ ss.	ʒ j.	ʒ iss.	ʒ ij.

12	24	ʒ ij.	℥ ss.	ʒ vj.	℥ j.

III. THE EXPRESSING OF A PRESCRIPTION.—A prescription is an order, *dated* and *signed*, to the pharmacist to take certain quantities of certain several substances; to perform upon them certain pharmaceutical operations; to label the package with certain directions concerning use, and to address it with the name of the patient. Upon this order the author may also have occasion to set down certain injunctions, such as "not to be renewed," or, "not to be shown to the patient," etc. In *form*, pre-

scriptions are commonly written after the following paradigm :

[*Not renewable without authority.*]

For Mr. A. B.

Take

Of substance *A*, quantity *x*.
Of substance *B*, quantity *y*.
Of substance *C*, quantity *z*, [etc.]

Do so-and-so [with them]......................
Label [the package]..............................

[*Signed*] C. D., M.D.,
No. 1 Blank Street.

[Dated] November 22, 1886.

Instead of a written signature, a very common and a very good plan, followed by many practitioners, is to have prescription-blanks printed for their personal use, bearing the imprint of name, address, and office-hours. In such case the imprint is commonly at the head of the paper. In *language*, a prescription is commonly written in part in Latin, and in part in the vernacular. In the United States the use of the Latin is commonly confined to such portion of the prescription as has to do with directions to the pharmacist for the compounding and "putting up" of the medicine; but in many other countries the *directions for use* are also written in Latin. This latter foreign custom has nothing to commend itself, but, on the contrary, is intrinsically objectionable on the score of opening an unnecessary doorway for the entry of mistakes. For such directions must, of necessity, finally appear in the vernacular in the label upon the package which is to serve for the patient's guidance; so that, to write them in the prescription in Latin is to entail their translation back into the vernacular at the hands of the pharmacist for the purpose of transcription, all at the risk of mistakes. Far better is the American custom, whereby the prescriber can—and always *ought*—set down, in the vernacular, in *fullest necessary detail*, the directions for administration, which directions are then simply to be copied, *exactly as written*, in the labelling of the package. Another, and quite universal, custom is to express by *abbreviation* or by *symbol*, in the pharmaceutical portion of the prescription, what might be called *staple* words. Thus, in the foregoing paradigm, *take* is expressed by the symbol "℞," which, originally the astronomical sign "♃," of the planet Jupiter (symbolical of the prayer to the deity Jove which in ancient times headed prescriptions), now bears its present peculiar form in order to do duty also as the initial letter of the Latin word *recipe*, signifying *take thou*. Next, titles of denominations of weight or measure are expressed by the commonly employed symbols for such denominations, and numeral adjectives by the so-called *Roman* numerals in the use of the *apothecaries'* system of weight or measure; but by the ordinary *Arabic* numerals when the prescription is by *metric* weight or measure, as is practically a necessity for the expression of the related integral and decimal fractions by which metric quantities are signified. Next, the word *misce*, signifying *mix thou*—the most commonly occurring word expressing requirement of pharmaceutical manipulation, is expressed by its initial letter *M.*, and similarly, and lastly, the word *signa*, signifying *label thou*, by its initial letter *S.* Other commonly employed abbreviations are "āā" for *ana*, latinized Greek for the phrase *of each*; "no." for *numero*, signifying *to the number of*; "q. s." for *quantum sufficiat*, signifying *as much as may be necessary*, and "p. r. n." for *pro re natâ*, signifying *according to need*.

It thus appears that all of the prescription requiring full dress in Latin is comprised in the titles of substances prescribed, and in the directions for the compounding. And for the correct latinizing of such items a critical knowledge of the Latin language, though, of course, of great advantage, is yet not indispensable. For, so far as relates to the expression of *medicine-titles*, all that is necessary is to know how to set these titles in proper *case*, and, as concerns the expression of *pharmaceutical directions*, it is to be remembered that, in the great majority of instances, the directions for compounding requiring specification in prescription-writing, are simple and set, so that their Latin phrasing is easily compassed by the knowledge of a few arbitrary words and phrases. Indeed, for all but seldom occurring exceptional directions, the latinizing can be effected by the words and phrases in the following list, properly coupled with the Latin words signifying forms of medicines, presumably already learned.

List of Odd Words and Phrases of Common Occurrence in the Expression of Pharmaceutical Directions, in Prescriptions.—1. *Verbs*, in *imperative mood*; "object" to be in the *accusative* case (analogue of the English *objective*):

Ádde, add.	*Fíltra*, filter.
Cóla, strain.	*Mácera*, macerate.
Dívide, divide.	*Mísce*, mix.
Exténde, spread.	*Sólve*, dissolve.
Fac, make.	*Tére*, rub.

2. *Verbs*, in *subjunctive mood*, taking a *subject* or a *predicate*, *nominative*:

Búlliat, let [it] boil.
Fíat, let [*it*] be made [into].
Fíant, let [*them*] be made [into].

3. *Verbal adjective* (participle) to agree with its noun in gender, number, and case:

Dividéndus (masculine); *-a* (feminine); *-um* (neuter), to be divided.

4. *Prepositions:* noun following to be in the *accusative* case:

Ad, to; up to. *In*, into. *Súpra*, upon.

5. *Prepositions:* noun following to be in the *ablative* case:

Cum, with. *Pro*, for.

6. *Miscellaneous Words and Phrases:*

Ána, of each.	*Guttátim*, by drops.
Béne, well,	*Non*, not.
Bis, twice.	*Sémel*, once.
Déin or *deínde*, thereupon.	*Símul*, together.
Et, and.	*Státim*, at once.
Gradátim, gradually.	*Ter*, thrice.

In the instance of a pharmaceutical operation which cannot be expressed in Latin by the application of the foregoing vocabulary, the wise course, even for the Latin scholar, is to forego elegance and write the direction in the vernacular. Otherwise it might chance that the prescription overstep the pharmacist's capacity for translation, to the obvious defeat of the compounding.

As regards the rendering, in proper Latin case, of the titles of the ingredient substances of a prescription, the points are as follows: There are, in Latin, six cases in the declension of nouns and adjectives, but of these cases four only are concerned in the latinizing of medicine-titles. These four are, respectively, as follows: The *nominative* case, corresponding to the English nominative, is the case in which titular words stand in simple statement—by which, in short, names are learned. Thus we recognize prepared chalk by the Latin title *Creta præparata*, wherein the two words of the title are in the nominative case. Next, the *genitive* case corresponds to the English *objective* case after the preposition *of*, and is the case in which titular words most commonly stand in prescription-writing. For, in the first place, *compound* titles, even in simple statement, commonly afford an instance of the genitive, as in the case of the title *tincture of opium*. Here the phrase *of opium* is rendered in Latin by the word *opium* set in the genitive case. Then, in the second place, in prescribing, the order for the "taking" of a given ingredient is, in the enormous majority of instances, a direction for the taking of a specified *quantity of* the substance in question. A prescription for a phial of laudanum, that is, will read: "Take *of* tincture of opium one-half fluidounce." In such case the titular word of the preparation itself—in this instance the word *tincture*—will have to stand in the genitive, since now it, also, follows the preposition *of*. With the exception, therefore, of a few conditions when titular words stand, in prescription-expression, in the *accusative*, the rule is that all titular nouns and adjectives which, in simple statement of the title, stand in the *nominative*, require, in prescription-orders, to be set in the *genitive*.

The third Latin case that concerns the prescriber is

the *accusative*, the Latin analogue of the English *objective following a transitive verb*. Titular nouns and adjectives take the accusative under the two following circumstances: First, when the order is not the common one to take a certain specified measure or weight *of* the thing, but to take *the thing itself* in a conditioned entirety. A common instance of this circumstance is where yolk or white of egg is an ingredient of a prescription. Here by the condition of things it is easiest to measure quantity by the natural measure of the egg-substance itself. Hence, in prescribing yolk the order is commonly to *take the yolk of one egg*, or of two, or of three eggs, as the case may be; in which case the title-word *yolk*, standing as the direct object of the transitive verb *take*, requires to be put in the accusative. Another commonly occurring instance where the accusative must appear, is where the prescriber writes for a certain *number* of a ready-made medicinal *entity*, such as pills or troches, of standard composition, and hence of independent title. Thus, to prescribe the pharmacopœial *compound cathartic pill*, the simplest way is to order directly the desired *number* of the already made pills, which the pharmacist keeps in stock. Such prescription, therefore, reads: "Take compound cathartic pills to the number of" so many, and so the word for *pills*, with its dependent adjectives, appearing as the immediate object of the verb *take*, stands in the accusative. The second circumstance determining the setting in the accusative of titular nouns and adjectives occurs, in one form of writing, in cases where the prescription orders that a given substance be taken *up to the attainment of a certain total bulk or weight.* This form of order most commonly obtains in the prescription of fluid mixtures, where it is often convenient to order in specified quantities the necessary amounts, respectively, of basis or adjuvant; but, as regards the inert *vehicle*, to simply direct the compounder to "take" the vehicle substance until the whole mixture shall attain the measure of the desired bottleful. In such case the order for the vehicle may be phrased in either of two styles—in the one of which the titular words will appear as usual in the genitive, but, in the other, in the accusative. The phrase in the latter style is according to the model, *take so-and-so up to [the measure of] so much.* Here the title of the substance "taken" is the immediate object of the verb *take*, and therefore stands in the accusative; the phrase *up to the measure of* being expressed by the preposition *ad*. The other style of phrasing the order is after this model: *Take of so-and-so as much as may be necessary to attain the measure of so much.* Here the title of the medicine once more follows the preposition *of*, and hence appears in the genitive. In the rendering of the order in this style, the Latin phrase *quantum sufficiat ad* (commonly abbreviated to *q. s. ad*) is the translation of the English "as much as may be necessary to attain the measure of."

The fourth and last Latin case that concerns the prescriber is the *ablative*, a case corresponding to the English objective after certain prepositions. The prepositions governing the ablative that occur in prescription-writing are *cum*, "with," and *pro*, "for." The former of these occurs in a few titles, as for instance, *Hydrargyrum cum Cretâ*, mercury with chalk; *Emplastrum Picis cum Cantharide*, pitch plaster with cantharides; and the latter in the much-used phrase *pro re natâ*, "according to need." But as regards the ablative, the special point obtains that the circumstances of prescription-phrasing never require the rendering in the ablative of a title-word which in the title appears in a different case. The few instances of the ablative in medicine-titles are therefore fixed, and the ablatives so occurring are easily learned by rote.

The *expression* of case is, in Latin, effected by modification of the ending of the word itself which is to be declined, and in such modification, *adjectives* share as well as nouns. Different modifications are employed to signify case in the singular and plural number, respectively, and of such modifications there are, in ordinary, five distinct systems, constituting the five several *declensions* of nouns and adjectives, besides cases of irregular declension presented by certain pronouns and cardinal numerals. Of the five systematic declensions, one, the *fifth*, affords but a single example in prescription Latin, namely, the ablative *re* of the noun *res* in the oft-quoted phrase *pro re natâ.* Of the other four declensions, examples occur in prescription-writing, of the *nominative, genitive, accusative* and *ablative* cases, respectively, in the singular number, and of the *nominative, genitive,* and *accusative* in the plural. The following table shows the endings for the several cases so enumerated, so far as concerns nouns and adjectives embraced in the prescriber's vocabulary. Endings for nouns not in such vocabulary are purposely omitted, as are also the irregular declensions of pronouns. In the table the italicised letters *m., f.,* and *n.*, signify respectively, that the case-endings in the columns beneath are those of nouns or adjectives of the *masculine, feminine,* or *neuter* gender; for, as appears in the table, case-endings often differ, even in the same declension, according to the gender of the word. The endings of the first and second declensions, severally, which appear *in parenthesis*, are the endings of certain Greek nouns, adopted into Latin with something of the Greek form retained. The table also gives a list of words of foreign origin applied as drug-titles, which, following the Latin idiom in such case, make no change of ending to signify case—are, in short, *indeclinable.*

TABLE OF PARTS OF LATIN DECLENSIONS SO FAR AS EXEMPLIFIED BY WORDS USED IN PRESCRIPTION-WRITING.

1. *Regular Declensions of Nouns and Adjectives.*

	First Declension.	Second Declension.		Third Declension.		Fourth Declension.
	f.	*m.**	*n.*	*m. and f.*	*n.*	*m.*†
SINGULAR:						
Nominative..	-a (-e)	-us (-os)	-um (-on)	(various)	(various)	-us
Genitive......	-æ (-es)	-i		-is		-ûs
Accusative....	-am (-en)	-um (-on)		-em	(like nom.)	-um
Ablative......	-à	-o		-e		
PLURAL:						
Nominative...	-æ	-i	-a	-es	-a	-us
Genitive......	-arum	-orum		-um, -ium		-uum
Accusative....	-as	-os	-a	-es	-a	-us

(Fifth Declension exemplified only in ablative singular *re* in phrase *pro re natâ.*)

* Except *juniperus, prunus, sambucus,* and *ulmus*, feminine.

† Except *cornus* and *quercus*, feminine.

2. *Declension of Cardinal Numerals.*

	Unus, One.			*Duo*, Two.			*Tres*, Three.	
	m.	*f.*	*n.*	*m.*	*f.*	*n.*	*m. and f.*	*n.*
Nominative..	un-us	-a	-um	du-o	-æ	-o	tr -es	ia
Genitive		-ius		-orum	-arum	-orum	-ium	
Accusative...	-um	-am	-um	-os	-as	-o	-es	-ia

All other cardinal numerals are indeclinable.

INDECLINABLE DRUG-TITLES—*all neuter.*

Amyl,	Coca,	Kino,
Azederach,	Curare,	Matico,
Buchu,	Elixir,	Sago,
Cajuputi,	Jaborandi,	Sassafras,
Catechu,	Kamala,	Sumbul.

As appears at a glance from the foregoing table, in the case of any noun or adjective belonging to either of the three declensions numbered as *first, second,* and *fourth*, respectively, if the *nominative* be given, any other case can be at once formed by substituting the proper case-ending for that of the nominative. In words of the *third* declension, however, this possibility in very many cases does not obtain. For in this declension the *nominative* often stands apart from the other cases in the way of having the very root, or "stem," of the word curtailed or modified in its construction. Thus, the stem *anthemid-*, giving genitive *anthemidis*, accusative *anthemidem*, and ablative *anthemide*, gives nominative *anthemis*—a word in which the full stem does not appear. Similarly, the root *flor-*, giving genitive *floris*, etc., gives nominative *flos;* and root *rho-*, giving genitive *rhois*, offers the much modified nominative form *rhus.* Hence, for the proper

rendering in oblique case of nouns or adjectives of the *third* declension, it becomes necessary to learn arbitrarily the form of some one of the oblique cases—most conveniently the genitive—as well as that of the nominative.

A special point concerned in the expression of case obtains in the case of *adjectives*, to the effect that very many of these words form their case-endings after different ones of the declension-models, according to the *gender* of the noun to which the adjective is attached. In compound drug-titles, therefore, which include an adjective, the gender of the noun modified by the adjective becomes necessary to know for the *intelligent*, proper rendering of the adjective's case-ending. Of course, such knowledge is not essential, since the title, adjective and all, can be learned by rote, and then, remembering the nominative form of the adjective, the necessary change to genitive or accusative, to suit the requirement of the prescription-phrase, can be done by rule. But it saves a vast amount of unnecessary memorizing to understand the system, so far as system goes, by which genders of Latin nouns are determined. Reverting, then, to the above declension-table, it appears that all prescription-occurring nouns of the *first* declension are *feminine* in gender; all those of the *second* declension ending in *-um*, or *-on*, are neuter, and, with a few exceptions, all of the *second* declension ending in *-us*, or *-os*, and all of the *fourth* declension ending in *-us*, are *masculine*. The exceptions in the two latter instances are nouns in *-us*, representing ancient Latin *tree-names*, which, because of the ancient Latin conception of an inherent feminity in trees as things, take the feminine gender in spite of their etymologically masculine nominative ending. In the *third* declension all genders appear, and, although in nouns of certain nominative-endings the ending carries with it the gender, yet in the case of many other nouns this is not so, and genders must be learned arbitrarily. Happily, however, the number of nouns of the third declension, among drug-titles, which bear an associated adjective, are quite few.

From the above analysis it is evident that, in the case of a given *noun* in the nominative, the rendering of the same in an oblique case can proceed by rule according to the foregoing declension-table, if only the declension of the noun be known; with the further item, in the instance of a noun of the *third* declension, that some one oblique case, as well as the nominative, be known, for the affording of the full stem of the word. Similarly, the proper case-dress of any given *adjective* can be fixed if the scheme of declension of the adjective itself be known, on the one hand, and, on the other, the gender of the noun to which the adjective is to be affixed—adjectives requiring to agree with their respective nouns in gender, number, and case. This requisite information concerning nouns and adjectives of prescription-use is afforded in the two following tables—the one giving a key to the declensions of nouns, with genders, and also, in the case of nouns of the third declension, genitive endings—and the other showing the schemes of declension of adjectives.

TABLE SHOWING DECLENSION AND GENDER OF NOUNS OCCURRING IN TITLES OF U. S. PHARMACOPŒIAL MEDICINES AND IN COMMON PRESCRIPTION-TERMS.

Nominative singular ending in **-a**:

All First Declension and Feminine, except (of Greek origin) *the following* in *-ma*:

Physosti′gma (physostig′matis), 3*d*, *n*.	E′nema (ene′matis), 3*d*, *n*.
[Aspidospe′rma (aspidospe′rmatis), 3*d*, *n*.]	Catapla′sma (catapla′smatis), 3*d*, n.
	Gargari′sma (gargari′smatis), 3*d*, *n*.

Nominative Singular ending in **-e**:

All First Declension, Feminine (Greek nouns).

[N.B.—Nouns in *-e* of Third Declension do not occur in prescription-writing.]

Nominative Singular ending in **-us**:

All Second Declension, Masculine, except—

Juni′perus, 2*d*, *f*.	Fru′ctus, 4*th*, *m*.
Pru′nus, "	Spi′ritus, "
Sambu′cus, "	Co′rnus, 4*th*, *f*.
U′lmus, "	Que′rcus, "
Rhus (rho′is), 3*d*, *f*. ("rhus glabra").	

Nominative Singular ending in **-os**:

Comprise only the following—

Prinos, 2*d*, *m*.	Bos (bo′vis), 3*d*, *m*. or *f*.
Flos (flo′ris), 3*d*, *m*.	

Nominative Singular ending in **-um**:

All Second Declension, Neuter.

Nominative Singular ending in **-on**:

Comprise only the following—

Erythro′xylon, 2*d*, *n*.	Eri′geron (erigero′ntis), 3*d*, *n*.
Hæmato′xylon, "	Li′mon (limo′nis), 3*d*, *m*.
Toxicode′ndron, "	

Nouns of all other endings are of Third Declension, and are as follows:

Ending in **-c**:

Lac (la′ctis), *n*.

Ending in **-l**:

(*-al*)	(*-ol*)
Chlo′ral (chlora′lis),	A′lcohol (alcoho′lis), *n*.
(*-el*)	Thy′mol (thymo′lis), *n*.
Fel (fe′llis), *n*.	[*N.B.—Some authorities regard these nouns in -ol as indeclinable.*]
Mel (me′llis), *n*.	

Ending in **-en**:

Alu′men (alu′minis), *n*.	Se′men (se′minis), *n*.

Ending in **-o**:

(*-io*)	(*-ago*)
Confe′ctio (confectio′nis), *f*.	Mucila′go (mucila′ginis), *f*.
Emu′lsio (emulsio′nis), *f*.	Ustila′go (ustila′ginis), *f*.
Lo′tio (lotio′nis), *f*.	(*-bo* and *-po*)
Po′rtio (portio′nis), *f*.	Ca′rbo (carbo′nis), *m*.
Tritura′tio (trituratio′nis), *f*.	Pe′po (pepo′nis), *m*.
	Sa′po (sapo′nis), *m*.

Ending in **-r**:

(*-er*)	(*-or*)
Æ′ther (æ′theris), *m*.	Li′quor (li′quoris), *m*.
Pi′per (pi′peris), *n*.	(*-ur*)
Zi′ngiber (zingi′beris), *n*.	Su′lphur (su′lphuris), *n*.

Ending in **-s**:

(*-as*, genitive *-atis*)	(*-is*, genitive *-eris*)
Ace′tas (aceta′tis), *m*.	Pu′lvis (pu′lveris), *m*.
[*and all salt-names in -as.*]	(*-is*, genitive *-is*)
(*-as*, genitive *-adis*)	Ca′nnabis (ca′nnabis), *f*.
Ascle′pias (asclepi′adis), *f*.	Digita′lis (digita′lis), *f*.
(*-is*, genitive *-itis*)	Hydra′stis (hydra′stis), *f*.
A′rsenis (arseni′tis), *m*.	Sina′pis (sina′pis), *f*.
[*and all salt-names in -is.*]	(*-os*, *see ante.*)
(*-is*, genitive *-idis*)	(*-us*, *see ante.*)
A′nthemis (anthe′midis), *f*.	(*-ns*)
Ca′ntharis (cantha′ridis), *f*.	Ju′glans (jugla′ndis), *f*.
Colocy′nthis (colocy′nthidis), *f*.	(*-ps*)
Hamame′lis (hamame′lidis), *f*.	A′deps (a′dipis), *m*.
I′ris (i′ridis), *f*.	(*-rs*)
Ma′cis (ma′cidis), *f*.	Pars (pa′rtis), *f*.

Ending in **-x**:

(*-ax*)	(*-ix*)
Bo′rax (bora′cis), *m*.	Pix (pi′cis), *f*.
Sty′rax (styra′cis), *m*.	Ra′dix (radi′cis), *f*.
(*-ex*)	Sa′lix (sa′licis), *f*.
Co′rtex (co′rticis), *m*. and *f*.	(*-ux*)
Ru′mex (ru′micis), *f*.	Nux (nu′cis), *f*.
	(*-lx*)
	Calx (ca′lcis), *f*.

TABLE SHOWING SCHEMES OF DECLENSION AND GENDER OF ADJECTIVES OCCURRING IN U. S. PHARMACOPŒIAL MEDICINAL TITLES AND IN PRESCRIPTION-PHRASES.

SCHEME I.—*Second and First Declensions Combined.*

Masculine.	*Feminine.*	*Neuter.*
-us [2d dec.]	*-a* [1st dec.]	*-um* (*-on*) [2d dec.]

SCHEME II.—*Third Declension.*

Masculine and Feminine.	*Neuter.*
-is (genitive *-is*).	*-e* (genitive *-is*).

SCHEME III.—*Third Declension.*

Masculine and Feminine.	*Neuter.*
-ior (genitive *-ioris*).	*-ius* (genitive *-ioris*).

SCHEME IV.—*Third Declension.*

All Genders.

-ens (genitive singular *-entis*); (genitive plural *-entium*).
-or (genitive *-oris*).

In commentary upon the declension-schemes of adjectives set forth in the foregoing table, it may be stated that Scheme I. embraces by far the greater number of adjectives. In this scheme the neuter ending *-on*, borrowed from the Greek like the same ending among nouns of the second declension, finds among drug-titles but a single example, *diachylon*. Scheme II. embraces a few adjec-

tives only among those occurring in medicine-titles, and affords an example of the nominative-ending *-e* of the third declension, which does not occur among *nouns* of pharmacopœial titles. Scheme III. is a special scheme for the declension of the comparative of adjectives, and affords but a single example from among the adjectives of medicine-titles, namely, the adjective *fortior, fortius,* "stronger." Of Scheme IV. pharmacopœial adjectives give but two examples in *-ens*, namely, *effervescens* and *recens*, and but one in *-or*, namely, *tricolor*. A survey of the *genders* marked on the table shows that in every case a distinctive gender, where there is such, can be told from the adjective nominative ending, with the exception that, among adjective nominatives in *-us*, one, *fortius*, is of the third declension neuter, and belonging to the third scheme, whereas all other adjectives of this nominative are of the second declension masculine, and belong to the first scheme. .

A final point, concerning the expression of a prescription, is that, having regard to the fact that a *slip of the pen* on the part of the writer, or a *slip of the understanding* on the part of the pharmacist-reader of a prescription, may convert what was meant as a missive of mercy into a death-warrant, it most solemnly behooves the prescriber to execute his task *deliberately, thoughtfully*, and, in chirography, *legibly, abjuring all dangerous cloak-of-ignorance abbreviation of medicine-titles ;* and, finally, to fail not of that trusty safeguard against error, a *review of the paper* after the writing. *Edward Curtis.*

PRIAPISM. The term priapism is usually understood to signify an unnaturally prolonged erection. The erection may be imperfect, or may even exceed the normal state, and is usually unaccompanied by sexual desire. It can hardly be considered as a distinct disease, but is probably always symptomatic of some abnormal local condition, or of some nervous derangement. A few cases have been reported in which it has followed violent or excessive coitus. A case was reported by Mr. Callaway[1] in 1824. The man was forty-four years of age, and while intoxicated had connection. Priapism continued for sixteen days, when Mr. Callaway "made an incision into the left crus penis below the scrotum, and a large quantity of dark grumous blood with small coagula escaped," and in a few days the man returned to work. Mr. Luke[2] reported a case in which priapism came on after repeated connection, and lasted for about four months. It occurs in connection with inflammations, new-growths, and traumatisms of the genito-urinary apparatus. Neumann[3] reports a case of carcinoma of the posterior and inferior wall of the bladder, with perforation of the bladder-wall and peritonitis, in which priapism was present for thirty-one days. The disease had invaded the vesiculæ seminales, the vas deferens, and the left ureter. It had compressed the vessels and caused inflammation of the corpora cavernosa.

In gonorrhœal inflammation of the vesiculæ erections are frequent and may amount to priapism.

In a case at the Boston City Hospital, rupture of the urethra and corpora cavernosa followed a fall upon the perineum. External urethrotomy was done, and an unsuccessful attempt made to unite the corpora by suture of the fibrous sheath. Partial priapism was present during the latter portion of the case, but finally disappeared.

Priapism occurs in a certain proportion of cases of acute poisoning from cantharides.

Priapism is a not uncommon symptom in acute myelitis. Generally the erection is incomplete, but it often persists for days with slight variations in degree. Injuries of the spine and cord are liable to be followed by continued or recurrent priapism, or by turgescence without rigidity. In eighty-two cases of fracture of the spine tabulated from the records of the Boston City Hospital, priapism occurred in eighteen.[4] It is most common in connection with crushing of the cervical portion, rarer with that of the dorsal, and, according to Erb,[5] never occurs with fracture from the third lumbar vertebra downward.

Priapism has been noted in some cases of tumor or other disease of the cerebellum and pons varolii, and is said to occur frequently in hydrophobia and tetanus.

The treatment must be directed mainly toward the condition of which priapism is but a symptom, but the patient's comfort may often be greatly increased by local applications of cold water or evaporating lotions, or by the local use of opium. Suppositories or cold rectal injections may give some relief. Internally the bromides are most likely to be of service. *Abner Post.*

PRO-AMNION. This convenient term was introduced by Ed. van Beneden to designate that part of the *area embryonalis* at the sides and in front of the head of the developing embryo, which remains without mesoderm for a considerable period, so that the ectoderm and entoderm are brought in the region of the pro-amnion into immediate contact. As found in one stage of the rabbit, it has already been figured in this work, vol. ii., p. 303. A later stage in the rabbit, as seen in longitudinal section, is figured by Kölliker in his "Grundriss d. Entwickelungsges.," 2 Aufl., p. 107. We find that it had been observed in the chick by Remak, His, and Kölliker. Strahl was the first to direct special attention to it. It has since been observed by various writers; van Beneden and Julin have described it in the rabbit, Heape in the mole, and recently its exact history has been admirably worked out in the chick by Ravn. The pro-amnion, then, has been observed in representatives of the classes Reptilia, Aves, and Mammalia; hence, we may conclude that it is common to all Amniota. It will be remembered that the mesoderm grows out in all directions from the blastopore, or hinder end of the primitive streak. In a chick of twenty-seven hours, the front edge of the mesoderm is a somewhat irregular transverse line, which crosses the germinal area about at the front border of the head. This line is well shown in His's drawings, loc. cit., Pl., xii., Fig. 14. As the mesoderm expands, it does not grow forward in the median line, but does grow forward at the sides of the *area pellucida* in front of the head of the embryo. A space is thus enclosed between the mesoderm on each side; this space later becomes the pro-amnion; it contains no mesoderm. Later on, the lateral portions of the mesoderm approach the median line again, some distance in front of the head, so that now the pro-amniotic area is completely surrounded by mesoderm. We see, as the next phase of development, the head amniotic fold arising in such a position that the pro-amnion is embraced between the arc of this fold and the head of the embryo; the pro-amnion, therefore, constitutes the floor of the pit formed by the upgrowth of the head amnion. In the chick the pro-amnion never acquires any considerable development, but gradually disappears by encroachments of the mesoderm upon all sides, as has been well described by Ravn, whose Fig. 3, loc. cit., Pl. xxi., will serve to give a clear general notion of the relation of the pro-amnion to the head, and to the true amnion in the chick. The disappearance of the pro-amnion in the chick involves some curious appearances in sections of embryos, which have not been understood hitherto, but which Ravn has correctly and fully elucidated, so far as I can judge.

In the rabbit, according to van Beneden and Julin, whose observations have been confirmed to a certain extent by Kölliker and Heape, the rôle of the pro-amnion is more considerable. The history of the pro-amnion, as given by van Beneden, may be followed easily by the aid of the accompanying diagrams (Fig. 3102), copied from van Beneden. In A, the pro-amnion, *pro.A*, is very small, and the allantois, *Al*, is just growing out. In B, the embryo, which for greater clearness has been shaded with stippling, has grown very much, and the anterior half of its body is bent down at a sharp angle into the yolk-sac. The embryo, however, remains separated from the cavity *Y*, of the yolk-sac, by the pro-amnion, which forms as it were a hood, *pro.A*, over the anterior

extremity of the embryo. The amnion proper is as yet developed only over the posterior end of the embryo. For the further history of the amnion see Amnion, vol. i. of this HANDBOOK. The pro-amnion, as can be seen in C and D, retains its importance as a fœtal covering for a considerable period, during which the amnion *am*, and allantois *Al*, are rapidly pursuing their development. After the stage shown in Fig. 3102, D, by the expansion of the cavity marked Coe', the amnion proper, *am*, encroaches more and more upon the pro-amnion, *pro.A*, until at last the embryo is entirely covered by the true amnion, and the pro-amnion is altogether lost. It is to be noted especially that the amnion develops principally over the posterior end of the embryo, and grows forward. To this fact reference will be made again directly.

We possess no observations at present, as to the existence of a pro-amnion in man, but from what we know of the early stages, we may conclude that it disappears quite soon after its origin; for we may assume that it occurs in man, since it has been demonstrated in all classes of amniota. This deduction renders it improbable to my mind that His's hypothesis of the formation of the human amnion is quite correct. We see, in fact, that in the amniota generally the principal growth of the amnion is from the allantois or allantois stock, when the allantois is rudimentary. This growth extends far forward, as in the rabbit—a point just mentioned. It is unlikely that man forms an exception to a rule of such wide application, in regard to an organ phylogenetically so ancient. It is a well-known rule that the older an organ in the evolutionary series, the less does its mode of development vary in any essential respect from species to species.

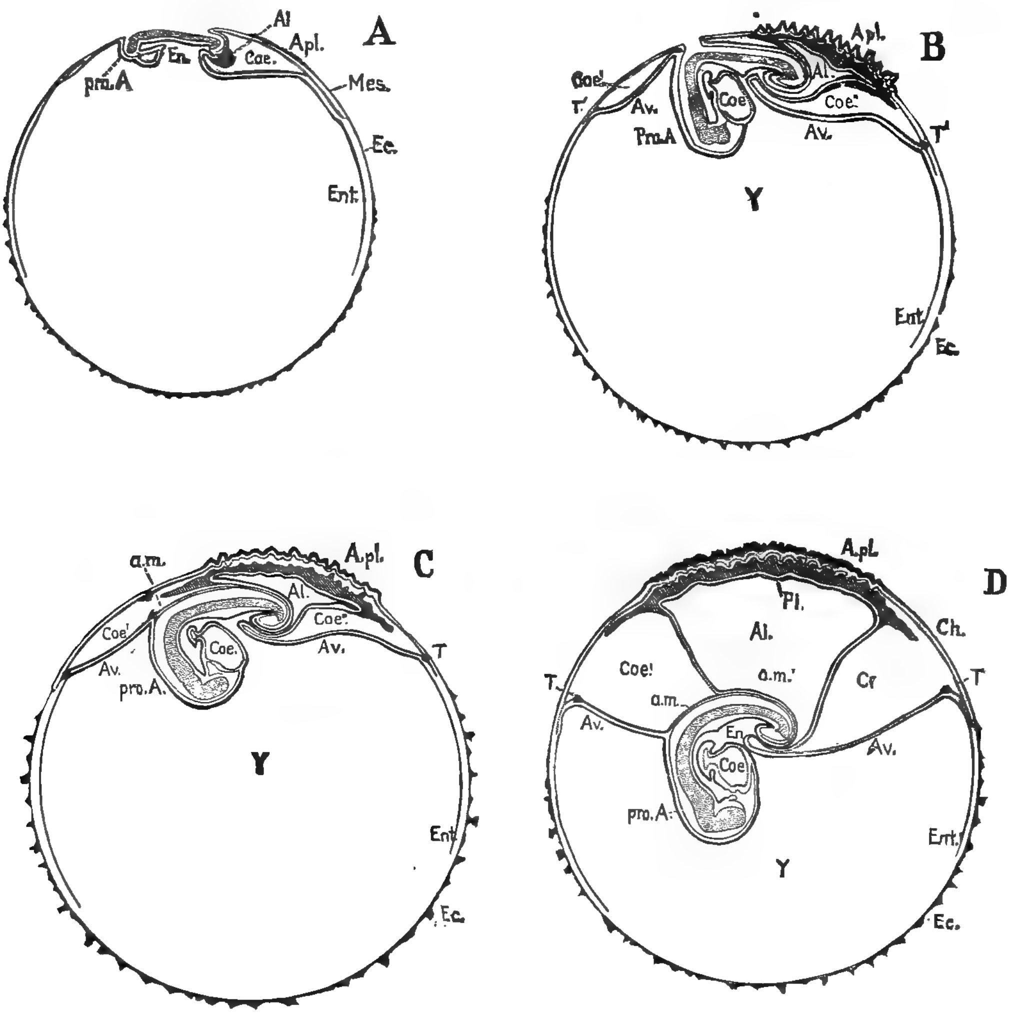

FIG. 3102.—Diagram of the Development of the Fœtal Adnexa in the Rabbit. (After van Beneden and Julin.) A, B, C, D, successive stages; *pro.A*, pro-amnion; *Av*, area vasculosa; *Coe*, cœlom; *Coe'*, *Coe''*, extra-embryonic portion of the cœlom; *En*, entodermic cavity of the embryo; *Ent*, extra-embryonic entoderm; *Ec*, ectoderm; *Mes*, mesoderm; *Apl*, area placentalis; *Al*, allantois; *T*, terminal sinus of the area vasculosa; *Y*, yolk-sac; *am*, amnion; *am'*, portion of the amnion united with the wall of the allantois; *Ch*, chorion.

PROFESSIONAL NEUROSES. SYNONYMS.—Beschäftigungsneurosen, Professional Dyskinesiæ, Nevrose coordinatrice professionnelle, Anapeiratic Paralysis, Neural Disorders of Writers and Artisans.

DEFINITION.—Under the term professional neuroses is

included a class of spasmodic and co-ordinative disturbances mainly of functional origin, affecting the groups of muscles used in special kinds of muscular work.

While spasm and co-ordinative disturbance are the main and typical features, paresis, sensory disturbances, vaso-motor phenomena, and general nervous symptoms are also present.

FORMS.—Every class of work, or form of occupation, which calls for continual use of the same groups of muscles, furnishes examples of professional neuroses. The upper extremities are, however, naturally the parts chiefly affected. Those professions in which the smaller and more delicately adjusted muscular groups are brought into play, furnish the largest contingent. The list of names for the various forms of professional neuroses increases almost every year, and now includes: Writers' cramp; telegraphers' cramp; milkers' cramp; musicians' cramp, including pianists', violinists', flutists', and elocutionists' cramp; tailors' and seamstresses' cramp; blacksmiths' and carpenters' cramp, or hammer-cramp; dancers' cramp; photographers' cramp; watchmakers' cramp; cigarmakers' cramp; auctioneers' cramp; swimmers' cramp; sawyers' cramp.

HISTORY.—We hear nothing of any of these now numerous neuroses until about fifty years ago. Dr. Bern. Ramazini, who in 1746 wrote a work on the diseases of tradesmen, does not describe writers' cramp, although he speaks of the diseases which come from the sedentary life of the clerk. Ramazini says, that the causes of the "*morbi scriborum*" are "continua sessio, manus perpetua et eodem semper tenore motio, mentis attentio ne libros erroribus conspurcent." He cites only one case, that of paresis of the arm, which at all suggests writers' cramp. The disease, therefore, is undoubtedly a product of the present century. The idea that the Emperor Augustus had writers' cramp is based merely on a single sentence in Suetonius. The first to refer to the disease was Sir Charles Bell, who gives a brief account of a case of writers' cramp in his work on the nerves, published in 1830. A year later, a case was reported in Germany by Brück, and at about the same time one by Gierl. In the next four years, a number of German writers reported their observations of the disease. Cazenave, in 1835, was the first French writer upon the subject. In this country Weir Mitchell, Beard, Hammond, and Lewis have written specially upon it. In the past fifteen years the literature of professional neuroses has been continually enriched by the contributions of writers from various countries.

WRITERS' CRAMP (Syn.: Scriveners' palsy, mogographia, graphospasm, steel-pen palsy, chorea scriptorum).

Etiology.—As the disease is one of this century, it is most probable that the influences of our present civilization, by increasing the neuropathic constitution, furnish a larger material for writers' cramp. For a neuropathic history is present in many cases, and all writers, except Beard, agree that it is this class which is peculiarly liable to the disorder. A history of some family nervous affection, such as chorea, epilepsy, or insanity, is obtained in a minor proportion of cases. On the other hand, it is strikingly true that some victims of writers' cramp are strong and robust in every way. The explanation here is that such persons overwork themselves to a degree exceeding that which nervous and delicate persons can do. Those who write a beautiful hand are more liable to the affection than poor writers, for the reason, chiefly, that poor writers get no position in which they can overuse their writing-muscles. The introduction of steel pens (1820 to 1830) corresponds with the appearance of writers' cramp, and there is no doubt that the use of steel pens tends to favor this disease, owing doubtless to the roughness of the end. Besides this, steel pen-holders continually carry away heat from the fingers, thus tending to lower vitality, and are difficult to grasp firmly. Writers soon learn that wooden, rubber, or cork holders are safer. The introduction of stylographic pens, and especially of type-writers, may lessen the relative amount of writers' cramp, just as steel pens at one time increased it.

Americans ought, theoretically, to be very subject to writers' cramp. So far as I can learn, however, this is not the case, and, in my opinion, in New York City the disease is a somewhat rare one.

Men are much more subject to the disease than women, though the difference is not so great now as formerly, owing to the greater number of women employed in writing.

Among thirty-one cases of typical writers' cramp observed by Poore, all were men. Women are more liable to have impairment of the writing-arm from pains and paresis, without having the true professional dyskinesis.

The average age in cases collected and observed by Lewis was twenty-seven (26.96) years. Among 64 cases of Berger's, 24, or nearly one-half, occurred between the ages of twenty and thirty, 12 between thirty and forty, 16 between forty and fifty, 7 between fifty and sixty, 5 between sixty and seventy. On the other hand, Dr. J. Russell Reynolds's cases were all over thirty, and Dr. Hammond's cases all over forty. The cases which I have seen have all been a little over thirty. The disease occurs, therefore, very rarely before twenty, and most often at about the age of thirty.

The use of alcohol or tobacco in excess, onanism, and other sexual excesses, emotional disturbances, and worry, all predispose to the disease.

The exciting cause is the abuse of writing. In ordinary writing about four motions of flexure, extension, and lateral movement are made for each word. Calculating at the rate of five letters for a word, and twenty words per minute as the rate of writing, this would be two hundred and forty-five thousand muscular contractions in a working day of eight hours. When the speed is increased, and the hours of work lengthened, under the pressure of a desire to earn more or to complete a task, it is easy to understand how the nerve-cells may become exhausted, or refuse to work together. Persons who do copying or routine work are much more liable to the affection, but it is largely because they abuse their writing-powers. Persons who write as they compose—authors, literary men, clergymen—are not so subject to the trouble, because they necessarily rest more in their work. Brain-workers are, therefore, as a rule, exempt from writers' cramp.

Berger and Erlenmeyer seem to think that the "American method" of writing specially tends to produce cramp. The contrary is, I think, true. In the American, or free-hand, mode of writing, as taught in most of our schools, the wrist does not touch the paper, and the hand is just supported by the little finger, the motion being made largely by the whole arm.

Debilitating disease may lead to a development of writers' cramp. Weir Mitchell reports two cases occurring in patients who had albuminuria. The symptoms were relieved when the albuminuria was treated. Lead poisoning (Berger), exposure to cold and rheumatic influences, injuries of the arm, tight sleeves, ingrowing nails, the pressure of a sleeve-button on the ulnar nerve, have all been mentioned as exciting causes of the affection.

Pathological Anatomy.—Neuritis is undoubtedly present in some forms of writers' cramp, so-called. It is not present, however, so far as external tests go, in the typical neurosis. Nor are there any post-mortem observations throwing light on the anatomy of the disease.

Pathology.—We must believe, therefore, that it is a neurosis, having no appreciable anatomical basis.

The act of writing is a very complicated one, calling into play numerous sets of delicately innervated muscles.

These muscles are employed: 1, in pen-prehension; 2, in pen-movement; 3, in holding the arm and wrist tense.

1. The muscles employed in pen-prehension are the two outer lumbricales, two outer interossei, the adductor muscles of the thumb, the flexor longus pollicis; to some extent the deep and superficial, short and long flexors, and the extensors of the thumb. These are supplied mostly by the ulnar (interossei, adductor pollicis, inner heads of deep flexor of fingers, and inner head of short flexor of thumb). The rest of the muscles are supplied

by the median. (I cannot understand Poore's statement, that the muscles of pen-prehension are innervated by the median and musculo-spiral.) The spinal centre for these muscles, *i.e.*, for the intrinsic muscles of the hand, and for the extensors of the thumb and flexors of the fingers, is situated at the level of the eighth cervical and first dorsal nerves, and the cell-groups are probably the anterior and median.

2. In moving the pen, if the writing is done mainly by finger, and not by arm, movements, the muscles brought into play, according to Poore, are the flexor longus pollicis, extensor secundi internodii pollicis, flexor profundus digitorum, extensor communis digitorum, and to some extent the interossei. The musculo-spiral and ulnar nerves innervate these groups about equally. In moving the pen by the "American" or free-hand method, there is a very slight play of the above muscles, while most of the pen movement is done by the muscles of the upper arm and shoulder, viz., the teres major, pectorales, latissimus dorsi, biceps, and triceps.

The spinal centres for these muscles are distributed along the fifth, sixth, and seventh cervical segments of the cord. The cells are larger, and situated more superficially, in the anterior gray horns.

3. Besides these movements involved in pen-prehension, and in the letter-making, a certain amount of muscular tension is exercised in "poising" the forearm and hand and steadying the wrist. The biceps and triceps, the supinators and the flexors, and extensors of the hand are here brought into play.

From the foregoing it will be seen that the muscles of pen-prehension are most used in all but the free-hand style of writing, since the same groups have a double duty, that of clasping and of moving the instrument. That this prehension group is oftenest affected is shown by the following table, compiled by Poore from a study of thirty-two cases of undoubted writers' cramp. He found the muscles affected in the following proportions: Interossei (supplied by the ulnar), 18 times; extensors of thumb (supplied by musculo-spiral), 10 times; flexor brevis pollicis (supplied by median and ulnar), 7 times; abductor pollicis (supplied by median), 7 times; flexor longus pollicis (supplied by median), 4 times; adductor pollicis (supplied by ulnar), 3 times; opponens pollicis (supplied by median), 2 times; all the muscles of forearm, more or less, 2 times.

While writers' cramp is often complicated with some neurotic disturbance leading to associated symptoms of pain, paralysis, tenderness over nerves, vaso-motor disturbances, etc., there can be no doubt that the lesion in typical cases is central. Writing is an acquired automatic movement, and it must have as its anatomical basis a certain established arrangement of nerve-cell groups in the cervical part of the spinal cord. The nerve impulses generated in the cerebral cortex pass along the pyramidal tracts and set at work those ganglion groups which, in turn, innervate the muscles used in writing with motor impulses. These groups are themselves innervated also sensorially by the nerves of muscle-sense in movement. In writers' cramp the spinal groups of cells are more or less used up or exhausted, and the motor impulse which naturally would innervate them strikes cells which respond unequally, or it overflows to other cell-groups, and hence the spasmodic, irregular movements of the arm.

The cerebral centres in the cortex are closely connected with those in the cord, and may be said to form part of the writing-mechanism. It happens in some cases that this centre too is exhausted and discharges its impulses irregularly. In some cases, therefore, the cerebral, and in some the spinal, cell-groups are the more affected, and a diagnosis of the exact condition in each is approximately possible, and may be not without practical importance.

Writers' cramp is a disorder of efferent paths and stations. The muscular sense does not seem to be involved.

The pathology of writers' cramp is that of all the other forms of professional neuroses, and nothing need be said upon this point regarding them when they come to be considered.

Symptomatology.—Writers' cramp very rarely attacks a person suddenly. The patient first notices a certain amount of stiffness occurring at times in the fingers, or the pen is carried with some uncertainty, and jerky movements are made. He feels a sensation of fatigue in the hand and arm, and this may amount to an actual tired pain. The first symptoms may last for months or even years. The hand is rested as much as possible, new pens or pen-holders, and new modes of holding it, are tried. Often the patient, fearing the onset of the cramp, and as its result loss of employment, becomes anxious, worried, and mentally depressed. Sometimes the trouble is worse when beginning a daily task, and it gradually wears off in a few hours. At other times exactly the reverse is the case. When the disease has reached its highest stage, writing becomes almost or entirely impossible. The moment the pen is taken in the hand and an attempt at using it made, spasmodic contractions of some of the fingers, or even of the arm, occur, the pen flies in any direction, and it is impossible to control or co-ordinate the movements. In a well-marked case, with the history of which I am acquainted, the patient, when called upon to sign a check, was obliged to make an unintelligible scrawl, which was attested to by witnesses. The rule is that, although writing cannot be done, all other complex movements are performed as well as ever. Thus the sufferer from writers' cramp may be able to play the piano, or paint, or thread a needle, or use the hand in any complex movements. Telegraphers, however, who use to some extent the same muscles as in writing, and who also often have to do a great deal of writing, are liable to suffer from both writers' and telegraphers' cramp at the same time. No evidences of actual paralysis are present in the affected muscles, and there is rarely anæsthesia, but the arm aches and is sometimes tender. Sensations of numbness and prickling are present; in rare cases vaso-motor disturbances are observed; associated muscular movements of the other arm, or of the neck or face, sometimes occur. The hand may tremble on attempting to write, or fall almost paralyzed when the pen is taken.

The various symptoms occur with different degrees of prominence, so that the disease has been classed under the heads of, 1, the spastic; 2, the paralytic, and 3, the tremulous type. To this Dr. Lewis adds, types with 4, sensory, and with 5, vaso-motor symptoms.

Such a classification is convenient, but it is to be remembered that in the majority of cases the forms are mixed.

1. The spastic form is undoubtedly the most common, and it has given to the disease its name. Cramp of some muscle or muscles was present in over half of Berger's cases of writers' cramp, and in thirty-one of Lewis' forty-three cases of telegraphers' cramp. The muscles of the thumb and first three fingers are oftenest affected, and in some cases the flexors, in some the extensors are chiefly involved. Canstett bases a classification upon this fact. In telegraphers' cramp it is the extensors, but in writers' cramp the flexors, that are mainly affected. The thumb, or fore-finger, or the little finger alone may suffer from the spasms. The pronators and supinators are quite often involved, and Berger notes a case in which there was spasm only in the pronator radii teres. Duchenne and Weir Mitchell report cases of "lock-cramp," in which, on attempting to write, the hand closes tightly in strong contraction, and remains so for a considerable time. This symptom suggests the hypertonia of Thomsen's disease. As stated, associated spasmodic movements sometimes occur in the neck muscles, or in the other arm.

With the spasm, there is also inco-ordination so far as writing movements are concerned, and this fact is quite as important in producing the bad writing as the spasm. The inco-ordination is apparently of the motor, or at least central, type, and is not due to anæsthesia of the muscle-sense, as in locomotor ataxia.

2. The paralytic form, or that type in which muscular feebleness is the dominant symptom, ranks next in frequency. In Berger's 64 cases, 24 were purely spastic, 10 paralytic, 8 tremulous, and 22 mixed.

In the typical paralytic form the patient, as soon as he begins to write, feels an overpowering sense of weakness and fatigue in the fingers and arm. The fingers themselves loosen their grip, and the pen may drop from the hand. Powerful impulses of the will and change in the mode of holding the pen, enable the sufferer to continue, but the arm aches, and finally is absolutely painful, and weakness and fatigue compel the writer to desist. Sometimes the paretic condition is succeeded by the spastic.

Many of the cases of paralytic writers' cramp are not true examples of the neurosis, but are rather cases of neuritis of a rheumatic or other type. Poore's tables show that nearly a third of the cases of impaired writing power are really forms of neuritic paresis. In this paralytic form the muscles of the thumb and the interossei are oftenest affected. The first dorsal interosseus and the abductor pollicis may be independently attacked. The writing, while writing is still possible, is fainter, and the characters larger as well as less perfectly formed. In the true cramp, the hand or arm muscles show no paresis, except in the act of writing; but in the neuritic impairment of writing, the paresis is absolute.

Duchenne records a case in which the lateral movements of the hand and arm along the paper were impossible. After writing a few words the patient had to draw the paper from right to left. In this instance the deltoid and infraspinatus were paralyzed.

3. The Tremulous Type. This, though rare, is very characteristic when present. The patient, when attempting to write, observes a tremulous movement of his hand and arm. This ceases when his attempts to write cease. The tremor usually affects most the fingers used in penprehension, but it generally spreads to the forearm, and may even involve the entire extremity. An oscillatory or lateral tremor, due to involvement of the pronators and supinators, has been observed by Cazenave.

The tremor, as may be seen, is of the character known as "intention-tremor," such as is observed in disseminated sclerosis. It is much shorter in range and more rapid than the tremor of that disease, and corresponds practically more with the ordinary fatigue tremor often seen after great muscular exertion.

General Symptoms.—Writers' cramp is essentially a motor neurosis, and its leading symptom is the impairment of a motor function. Other symptoms, however, both general and local, are always associated with it. These are mainly (1) psychical and (2) sensory, more rarely (3) vaso-motor, and (4) trophic.

1. Psychical Symptoms. The patient is often nervous, emotional, and mentally depressed at times. He suffers from insomnia and vertigo. Patients are generally unwilling to admit that there is any other trouble than the local one, and only careful examination may bring evidence of constitutional trouble. There are cases of purely mental "writers' cramp." Thus, Shever gives the history of a man forty-two years of age, who was suddenly attacked with vertigo. Next day he found that he could not write, because an inexplicable feeling of fright seized him when he began to form letters. His condition became ameliorated, so that he could write for a time, when again the fear would seize him. He could write with his eyes closed. There were no other symptoms. Dr. Morris J. Lewis, who has investigated the subject of telegraphers' cramp more thoroughly than anyone else in this country ("Pepper's System of Medicine," vol. v., p. 520), states that telegraph operators who suffer from cramp, are sometimes unable mentally to grasp the proper number of dots and dashes composing certain Morse characters. They also have special difficulty in making these characters and of recognizing them by sound. The dot-characters give the most trouble.

2. Sensory Troubles. These consist of pain, sense of fatigue, feelings of numbness, prickling, pressure, weight, tension, constriction, etc. Hyperæsthesia, and more rarely anæsthesia, are also observed.

The most common sensory symptom is that of aching and fatigue, and this is usually confined to the arm. The pain is especially noticed in connection with the paralytic form (Zuber), and it generally follows the course of the nerves. The radial and median are those chiefly involved, while very little pain is ever felt along the ulnar. The arm is tender along the course of the nerves, and there may be tenderness over the cervical vertebræ. Erb had a patient who suffered from a steady pain over the left frontal region, almost exactly, it seems, over the probable writing-centre. M. Meyer calls attention to the presence of pain and tenderness, at times, in the apophyses. Disturbance of the common sensibility of the muscles of the arm has been observed by Poore. In fine, the involved extremity may be affected with a great variety of subjective sensory disturbances.

3. Vaso-motor, Trophic, and Secretory Disturbances. The condition known as *digiti mortui* has been observed, coming on paroxysmally. It is a symptom which the general neurasthenic state helps to produce. When the nerves are involved, decided vascular changes may occur, such as passive congestion of the hand and arm, with swelling and turgescence of the fingers, and a sensation of throbbing. In bad cases the fingers will look as if they had chilblains. Local sweating, dryness of the skin, and cracking of the nails, all are conditions which may follow impairment of writing-power from neuritic causes.

Electrical Reactions.—The results of observations upon the electrical reactions of the affected parts are somewhat contradictory. Ordinary tests will, as a rule, reveal very little change. Sometimes there is a quantitative increase, sometimes a decrease, of irritability to both forms of current. The increase occurs in the earlier stages, the decrease in the later. The contraction formula, Ka C C > An C C, is not changed, unless a decided neuritis complicates or causes the trouble. An increase, or modification, of electro-muscular sensibility has been noted. The electrical examinations, therefore, are only of value in excluding a neuritis, or possibly in determining the stage of the disease.

Course and Duration.—Writers' cramp is a chronic disease. It begins insidiously, and attacks one group of muscles after another, as each is brought into play by new methods of writing. If the left hand is used, that, too, is liable to become affected. The course varies, however; for a time progress may be arrested, or improvement set in. When the disease becomes well established, it will most often last a lifetime. For example, a pianist, while yet a young man, was attacked with pianists' cramp. He changed his profession, and gave up piano-playing; yet, at the end of five years, if he attempted to use the piano, the cramp still attacked him.

Prognosis.—The prognosis is unfavorable, yet not so much so as has once been thought. Undoubted cases of complete recovery have been reported, and Berger's statistics place the per cent. as high as eight. I have observed a case of complete cure of telegraphers' cramp, and one of writers' cramp.

The prognosis is much more favorable if the patient begins treatment early, and before marked spastic symptoms are present. It is believed that certain modern therapeutical methods, to be referred to later, will also modify the prognosis. Some patients who suffer from a mild form of the trouble manage, by the help of instruments or special pens, to do their work for years.

The more acute the disease, and the more evidently peripheral and neuritic its origin, the better the prognosis. Severe sensory disturbances are of more favorable omen than severe motor trouble. Perhaps in about one-fourth of the cases, patients who use their sound arm will not be affected in it.

The facts stated regarding the cause, physiology, and general symptomatology of writers' cramp apply to the other forms of functional neuroses. A few special details, however, will be given regarding these. The most common and important are musicians' cramp and telegraphers' cramp.

Musicians' Cramp.—Under this head we include pianists' cramp, violinists' cramp, flutists' cramp, and the cramp of clarionet players.

Pianists' cramp occurs usually in young women who are studying to become professionals, or who are espe-

cially hard-working and ambitious. The absurd "Stuttgart method" of teaching the piano, in which the motions are confined as much as possible to the fingers, predisposes especially to this disease. The symptoms are those of fatigue, pain, and weakness. The pains are of an aching character. They are felt in the forearm especially, but extend up to the arm and between the shoulders. Spasmodic symptoms are rare. The right hand is oftener affected, but both hands eventually become involved.

Violinists' cramp may attack the right hand which holds the bow, or the left hand which fingers the strings, but more often the left hand is affected. The sufferer feels at first a sense of fatigue and uncertainty in the fingers and arm, then pain, and finally some spasmodic movements occur.

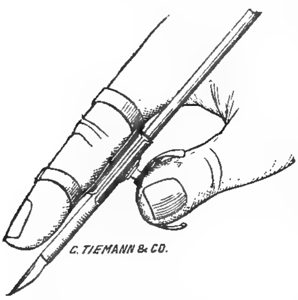

FIG. 3103. – Mathieu's Apparatus. The pen is moved by the thumb and index-finger.

Clarionet players sometimes suffer from cramp of the tongue (Strümpell), and of the laryngeal muscles (Eichhorst).

Flute players, according to observations related to me by Dr. T. H. Kellogg, suffer not very infrequently from slight laryngeal spasms. The same observer has noted similar spasms in elocutionists. The term mogophonia is applied to this trouble.

Telegraphers' cramp was first described by Simon, in 1878 (*Comptes rendus Soc. de Biol.*, 6, 92–96). It has been noticed by English and Scotch physicians, and has been exhaustively studied by Dr. Lewis, of Philadelphia (*loc. cit.*). Dr. Beard also made some studies of it. It affects especially those operators using the Morse system, an instrument which is still the one most widely in vogue. Contrary to the opinions of previous writers, Dr. Lewis believes that this neurosis is not a rare one, and is destined to become more frequent. Considering that there are perhaps less than thirty thousand telegraph operators in the country, as against the vast army of clerks, copyists, writers, etc., the fact that Dr. Lewis was able to collect forty-three cases of telegraphers' cramp is significant.

Dr. W. H. McEnroe, of New York City, who has had a largely personal experience with telegraph operators and their diseases, informs me that the cramp is rare, the proportion being about one in every two hundred.

The technical name, among operators, for the cramp is "loss of the grip." In telegraphing, the extensors of the wrist and fingers are called most into play, and hence are most and earliest affected. The symptoms come on very slowly, the thumb and index-finger being first affected. The victim finds that he cannot depress the key on account of spasm in these muscles, and he finds most difficulty in making the dot-characters, such as h (. . . .), or p (. . . . .), or z (. . . .). When the flexors are most affected, the key is depressed with undue force, and a dash is made instead of a dot. Sufferers from the "loss of grip" generally suffer from writers' cramp also. Most cases occur between the ages of twenty and thirty. Males and females are almost equally affected—perhaps there is a preponderance in favor of females; and, according to Lewis, the disease attacks them earlier than it does males. While spasm is usually present, the disease may show itself simply in pain, paresis, and incapacity to co-ordinate the muscles.

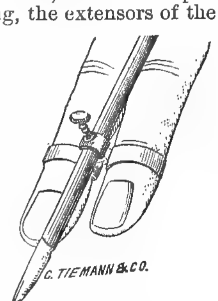

FIG. 3104.—Mathieu's Apparatus. The pen is held by the index- and middle-fingers.

In *sewing spasm*, which affects tailors, seamstresses, and shoemakers, clonic and tonic spasms attack the muscles of the hands on attempting to use them in the regular work. Tailors who sit cross-legged sometimes suffer from a peculiar spasm on assuming this position. It is possible, however, that these are cases of tetany, and not of the functional neurosis under consideration.

Smiths' spasm, crampe des forgerons, hephæstic hemiplegia, appears to have been observed only by Duchenne and Dr. Frank Smith (*Dictionnaire encyclop. des Sciences médicales*, t. x., p. 775). It occurs in persons engaged in pen-blade manufacturing, saw-straightening, razor-blade striking, scissors-making, file-forging, etc. In doing this work they have to use a light or heavy hammer, with which strokes are delivered very rapidly and carefully. After a time spasmodic movements occur in the arm used, and the arm falls powerless. As in the cases reported there are generally hemiplegic symptoms, and also neuralgias, vertigo, and other cerebral troubles, the disease cannot be a pure "professional" neurosis.

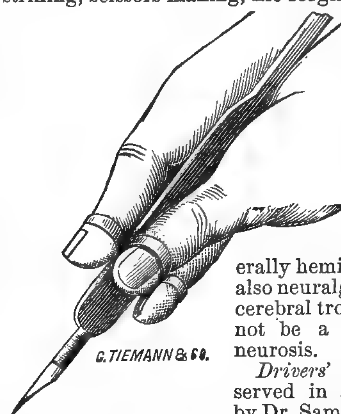

FIG. 3105.—Cazenave's Apparatus. The index, middle-finger, and thumb are immobilized.

Drivers' spasm has been observed in a veterinary surgeon by Dr. Samuel Wilkes ("Diseases of the Nervous System"). The patient had to drive hard-bitted horses for many hours daily. Finally his arms were attacked with cramps whenever he took the reins.

Milkers' spasm is an extremely rare affection, which was first described by Basedow and seems to occur in milkmaids, never in milkmen (*Casper's Wochenschr.*, 1851). Berger is the only other author who reports a case.

Cigarmakers' cramp must be an exceedingly rare affection. I can find reports upon it by only two observers, O. Berger (*Berlin. klin. Woch.*, 1873, No. 21), and Koster (*ibid.*, 1884).

Watchmakers' cramp (O. Berger, S. Weir Mitchell) and *Photographers' cramp* (H. Napias: *Revue d'Hygiène*, i., 927, 1879), are also to be regarded merely as pathological curiosities.

Ballet-dancers' Cramp.—Under this name certain painful and paralytic troubles occurring in ballet-dancers, especially premières danseuses, have been described by Schultz, Onimus, and Kraussold. It does not appear that

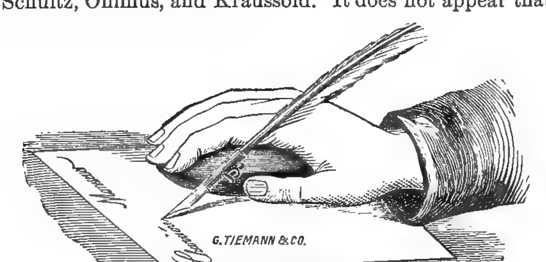

FIG. 3106.—Duchenne's Apparatus.

the trouble is really a co-ordinative functional one, but is rather neuralgic, or the result of local strain upon the parts.

The list of professional neuroses is made to include, besides those above given, cramps and co-ordinative troubles affecting artificial flower-makers, billiard-players, dentists, hide-dressers, electrical instrument-makers, stampers, turners, sewing-machine girls, money-counters, weavers, painters, and pedestrians.

In most of these cases there is probably some inflammatory affection of the nerves, or ligaments, and not a true central neurosis.

The Diagnosis of well-marked cases of writers' cramp presents no difficulty. In the earlier stages, however, it may be confounded with a large number of disorders, viz., post-hemiplegic chorea, hemiataxia, progressive muscular atrophy, progressive locomotor ataxia, various forms of tremor, lead paralysis, rheumatoid arthritis, neuritis, cerebral and nerve tumors, and tenosynovitis.

In many of these cases it is only necessary to bear in mind the history of the disease in order at once to reach

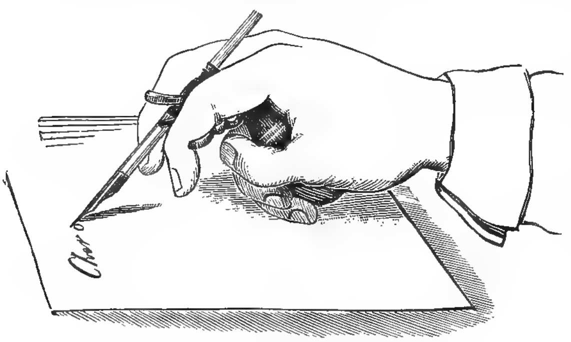

FIG. 3107.—Cazenave's Apparatus, Modified by Duchenne.

a diagnosis, for in writers', or telegraphers', or musicians' cramp the symptoms are localized in a single, or at most two, extremities.

Dr. Weir Mitchell has called attention to the fact that a person may have a very slight and transient cerebral hemiplegia, followed later by post-hemiplegic disorders of movement, which may be mistaken for writers' cramp. Such troubles occur either much earlier, or somewhat later, in life than the writers' cramp, and the motor disturbances affect the leg and possibly the face as well as the arm. Dr. Lewis (loc. cit.) cites from Dr. Weir Mitchell's note-books two cases, illustrating the fact that some cases of slight arm paralysis, due to small lesions affecting the arm-centre of the cortex, may be mistaken for functional paralysis.

Some occupations which call into play repeatedly and continuously the same group of muscles, produce in them a gradual atrophy. This has been called "professional muscular atrophy" by Onimus. I have seen it occur in the thenar muscles and deltoid of a butcher, whose work obliged him to handle a cleaver for many hours daily. I have also observed atrophy of the thenar muscles in a lapidary. The act of writing may induce a progressive paresis and atrophy of the muscles of pen-prehension. These occupation muscular atrophies are, I believe, myopathic in origin; they are not accompanied with the central vaso-motor or secretory disturbances of true spinal progressive muscular atrophy, and they are characterized by a rapid improvement or arrest in progress under rest and treatment. Dr. Lewis cites some cases to show that in the earlier stages, or in mild types of multiple sclerosis, or irregular diffuse sclerosis of the brain and cord, motor disturbances occur which may be mistaken for writers' cramp.

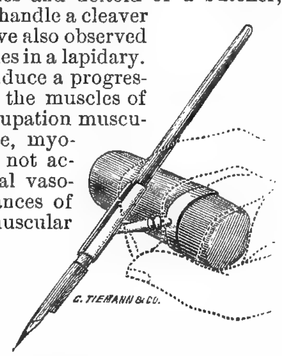

FIG. 3108.—The Pen is Attached to a Block, which is Grasped by the Hand in the Position Shown by the Dotted Lines.

As already stated, the diagnosis of the various "cramps" is practically easy when any ordinary care is exercised in examination; and, after all, the most important point for the physician to determine is the form of impaired writing-power from which the patient suffers.

If there is a great deal of pain in the arm, with tenderness along the course of the nerves; if there is decided change in the electrical reactions; if there are sensations of tingling, numbness, etc.; and if the patient shows an absolute loss of power in the various groups of muscles, with some incapacity for doing other acts besides the one with which he is specially concerned; then the trouble is undoubtedly peripheral and due largely to an underlying neuritis. The prognosis in these cases is much more favorable. If, on the other hand, the disorder comes on in persons who have not done an excessive amount of writing; if it is associated with nerve-strain; if the electrical reactions are but slightly changed, the sensory symptoms slight, and the motor inco-ordination marked, limited to the special class of work, and not accompanied with absolute paresis, the disorder is central, and needs both a different treatment and prognosis. It is these cases that form writers' cramp proper, although no doubt neuritic and central forms are associated, or the former may run into the latter.

For convenience I append a diagnostic table showing the differential points between central and peripheral writers' cramp:

IMPAIRED WRITING-POWER, ETC., MAINLY OF NEURITIC ORIGIN.	IMPAIRED WRITING-POWER, ETC., MAINLY CENTRAL IN ORIGIN.
1. Caused by excessive writing.	1. May be no marked excess of writing; but a neurotic history is obtained.
2. Marked sensory symptoms of tenderness over nerves.	2. Sensory symptoms subordinate. General nervousness and mental depression are noted.
3. Electrical reactions show increased irritability, possibly qualitative changes.	3. Electrical changes slight.
4. Paresis of certain groups of muscles. This may be shown in inability to do other co-ordinate acts.	4. Paresis but little marked or absent. Patient can do all other kinds of muscular work easily.

Prophylaxis and Treatment.—Although the amount of writing done at the present day is enormously increased, there is not a corresponding increase in writers' cramp. This is due to the introduction of gold and stylographic pens, type-writers, and better pen-holders. Persons who do a great deal of writing, if they find any signs of impending cramp, should use some of these instruments as much as possible. Stylographic pens are less liable to lead to trouble in writing, because not so much prehensive power is needed in their use. The same is true to a less extent of gold pens. The pen-holders should have a slightly roughened surface, of cork or soft rubber. Large-handled pen-holders are held more easily. Small, smooth, metal or hard-rubber holders are to be avoided. Pencils are not so good as pens, because they require more prehensive force. The paper written upon should be smooth. The best style of writing is that already referred to as the American, the movements being made both with the arm and the fingers. Many nervous persons have a bad habit of gripping the pen very tightly, and pressing down on the paper with excessive force. Fatigue soon results, and painful sensations develop in the arm. Proper attention should be paid to the position of the paper written upon, the height of the desk, the light, and the sleeves of the coat or dress. The paper should be laid at an oblique angle to the edge of the desk, and not at a right angle as many writing teachers are accustomed to direct. As some cases of "cramp" are undoubtedly cerebral, it is very unwise to attempt any extraordinary exploits in writing, or to work with the ambition to put the writing capacity to the utmost test. Cramp is often dated from days when such extra work is done. Sensations of weariness and

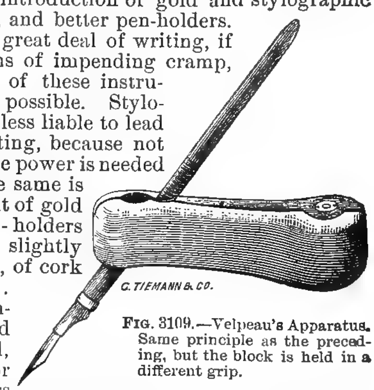

FIG. 3109.—Velpeau's Apparatus. Same principle as the preceding, but the block is held in a different grip.

slight premonitions of cramp should be watched and promptly treated. It seems to be agreed that no modification of the telegraphers' key is of much value in preventing "loss of grip." Telegraphing with the finger-movement alone, the wrist and fore-arm resting on the table, is a bad method that should be avoided.

When the cramp is fully developed, by far the most essential thing is prolonged rest, and the physician should always consider the question whether the patient should not abandon his occupation altogether. If complete rest is not attainable, the various methods of getting partial rest are as follows :

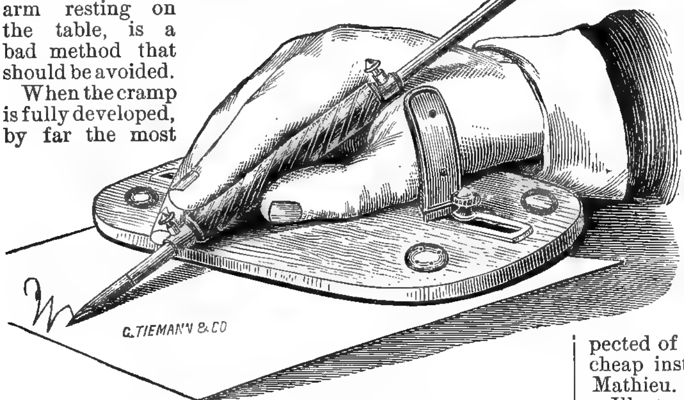

Fig. 3110.—Apparatus of MM. Charcot and Cazenave. The hand is fastened to a board, as is also the pen. The board slides along upon the paper.

1. Getting a new form of pen and pen-holder.

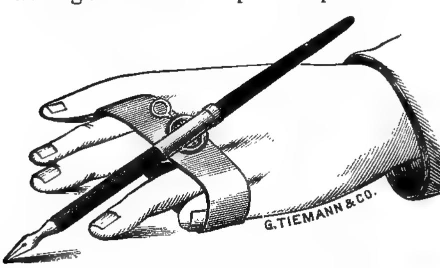

Fig. 3111.—Nussbaum's Apparatus. It consists of a bracelet of hard rubber, upon which the pen can be fastened at any length. In order to hold it firmly, the fingers have to be spread out. A piece of flannel is placed between the hand and the paper.

2. Holding the pen in a different way.
3. Using the unaffected arm.
4. Using some form of mechanical appliance.

With regard to 1 and 2, enough has already been said.

3. As a rule, if the unaffected arm is used, it soon becomes involved also. This is not always the case, however.

4. The mechanical appliances are splints, rubber bands around the wrist, and various instruments contrived to prevent spasm and throw the work of writing on new and larger groups of muscles.

Instruments for writers' cramp are very numerous. The first one was invented by M. Cazenave, in 1846, and simply fastened together and immobilized the thumb, forefinger, and middle-finger. M. Mathieu constructed several instruments which relieved the hand of the necessity of pen-prehension and immobilized the fingers—a matter of especial importance when there is paralysis. MM. Vulpian and Charrière devised a series of instruments in which the pen is fastened at various angles to a ball or bar, which latter is grasped by the hand. Prehension and the writing-movements are thus performed by a different and larger number of muscles.

As will be seen, the French have been particularly prolific in originating these instruments.

Mr. Charles Thurber, of Philadelphia, himself a sufferer from writers' cramp, invented an instrument which he called the "Kaligraph." It consists essentially of a pantograph so arranged that, by making the letters very large at one angle, they are reduced to a natural size at the other. Besides this, the writing is done entirely without any effort of pen-prehension, and may even be accomplished by attaching the directing pin to the wrist. The principles involved, therefore, are good, and practically it has been successful. It is, however, cumbersome and expensive. Professor Nussbaum has devised an apparatus involving a new principle. In order to write with it the fingers must be separated, and some effort must be made with the extensors, while none at all is made by the flexors of the fingers and the wrist. Hence, new sets of muscles are actively innervated while those ordinarily used are rested. Practically this instrument is often very helpful. All the various instruments have been of service, or have even been curative in some special cases, but not too much must be expected of them. As a rule, they are only palliative. A cheap instrument that may prove satisfactory is that of Mathieu.

Illustrations of the different instruments are given on this and the two preceding pages.

In the medical treatment of writers' cramp, the two most important agents are massage and electricity.

By massage only very mediocre results were obtained until greater attention was drawn to it by Mr. J. Wolff, a writing-master of Frankfort-on-the-Main. This gentleman has cured many cases, though not all that he has tried (Berger), and he has secured many testimonials for his method. It has only been fully described, however, by Drs. Schott and Stein, the former of whom disputes with Mr. Wolff the honor of devising the method. The treatment, as described by Schott (G. W. Jacoby : "Massage in Nervous Diseases," *Journal of Nervous and Mental Diseases*, June, 1886), consists of a system of gymnastics and massage.

The gymnastics consist of movements performed by the patient alone, and movements executed with the co-operation of the operator.

The first are performed by the patient during from twenty to thirty minutes, rarely for forty-five minutes. These movements consist of gymnastics of the fingers, extension, flexion, abduction, and adduction being performed, and the thumb being exercised separately. After this the same four motions are executed at the wrist-joint, then extension and flexion of the forearm, and ultimately the arms themselves are exercised in the same manner and are to be lifted over the head. Each single exercise is to be performed from six to twelve times. After each motion a pause is to be observed.

The opposed movements are to be carried out in the same manner, except that the operator must carefully resist their execution as though he were endeavoring to force the patient to perform a motion just the reverse of his intentions. Regularity of pressure is to be observed in this, so that the same amount of force is always used, and so that the pressure does not vary in intensity from

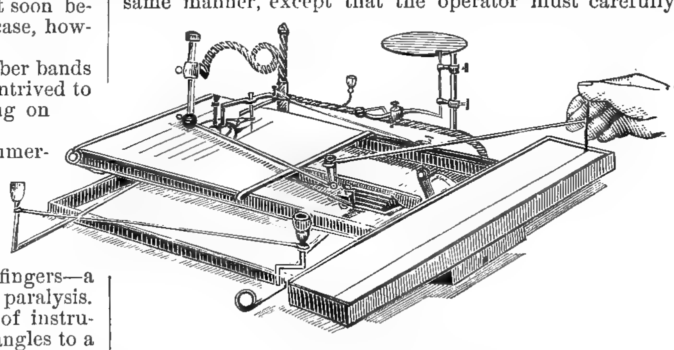

Fig. 3112.—Thurber's Kaligraph.

moment to moment. The time to be devoted to these opposed movements should be the same as that for the unopposed ones. According to the intensity of the affection, the exercises must be repeated two to three times daily.

The massage itself consists of two parts—nerve and muscle massage. The nerve-massage is effleurage along the course of the nerve-trunks, the median, ulnar, and radial, going upward to the axillary and cervical plexuses. This effleurage lasts about ten minutes. Following this is the muscle-massage. This consists of pétrissage, beginning with the hand and ending at the shoulder. The duration is the same as that of the last movement. One sitting a day has always proved sufficient.

Wolff, in addition, uses "a peculiar method of writing instruction," and employs rubber bands and rings in his manipulations. Wolff is by no means alone in getting good results from massage.

Electricity ranks second to massage in the treatment of professional neuroses. The faradic current may be used when the affection is paralytic, but the galvanic current is usually more efficacious. The polar method is to be employed, the anode or sedative pole being placed over the cervical spine, and the kathode over the various muscular groups affected. A stable current of five to ten milliampères for from ten to fifteen minutes is indicated. Galvanization of the sympathetic is recommended by some. Galvanic belts applied about the arm seem irrational enough, but have been known apparently to effect cures. Vigouroux claims to have cured a case by static electricity.

Lotions containing muriate of ammonia, liniments, hot and cold douches, the cautery, all have been recommended in professional neuroses. Tenotomy was once employed, but has been abandoned. Very little can be expected of drugs. The most trustworthy are: atropine, strychnine, the iodides and bromides, and cod-liver oil. It should be remembered that sometimes the disease is almost purely cerebral, and then an anti-neurasthenic treatment is called for. But in other cases, when the disorder is largely peripheral, the usual treatment for a low grade of myo-neuritis must be employed.

Charles Loomis Dana.

PROPYLAMINE. A body isomeric with *trimethylamine*, with which it is often confounded. See Trimethylamine.

PROSTATE, THE. The prostate gland (Gr. προστάτης, from προ and ἱστάναι, to set, or ἵστημι, I stand) derives its name from its position at the entrance to the bladder.

ANATOMY.—The prostate is a body largely glandular in character, and in shape much like a Spanish chestnut. In the upright position of the body it lies just below the bladder and behind the symphysis pubis. The base of this heart-shaped gland is in contact with the bladder and vesiculæ seminales, while the apex rests upon the posterior layer of the deep perineal fascia; the anterior surface looks toward the pubes, and the posterior surface rests upon the anterior rectal wall.

The urethra, as it leaves the bladder (pars prostatica urethræ), traverses the prostate from near the middle of its base to its apex, and rather more than one half of the gland lies behind the canal.

The prostate weighs from five to six drachms, and measures approximately one inch and a half in length, one and a half to two inches in breadth, and one inch in thickness (antero-posterior diameter). Slight longitudinal furrows along its anterior and posterior surfaces, show an indistinct tendency toward a division into two lateral lobes, although the two halves are structurally continuous with each other. In this connection it is worthy of note that in some animals the prostate consists of two separate lobes.

That portion of the gland lying between the ejaculatory ducts and the urethra (pars supra-montana, Mercier), is usually known as the middle lobe (Home). Situated upon the floor of the urethra, just at the entrance to the bladder, it often forms a little prominence continuous with an elevation of the vesical floor (uvula vesicæ).

The portions of the gland behind and in front of the urethra, connecting the lateral lobes, are known as the posterior and anterior commissures.

The substance of the prostate is made up mainly of three tissues: 1, Glands; 2, unstriped muscular fibres, and 3, fibrous tissue.

The glands are of the acinous variety, and are most abundant in the lateral portions of the organ, their ducts coalescing and opening along the floor of the urethra. The muscular fibres are disposed in circular bands which are continuous at the junction of the bladder with the circular fibres of that viscus. Hyrtl also describes a system of these fibres radiating from the caput gallinaginis. The fibrous tissue forms a firm enveloping capsule which sends off-shoots through the substance of the gland.

Just below the point of entry of the urethra the two ejaculatory ducts enter the prostate, one on each side, and running forward through its substance and converging, they enter the floor of the urethra.

The prostatic urethra (pars prostatica urethræ) is slightly narrower where it enters and leaves the gland than it is within it. The hollowed floor of this portion of the canal is called the sinus prostaticus, and is divided into two equal furrows by a longitudinal ridge (verumontanum), the end of which furthest from the bladder is composed of erectile tissue, and is capable of considerable dilatation into a little round prominence which, with the verumontanum running back from it, presents a fancied resemblance to the head of a snipe—hence its name *caput gallinaginis.*

On the top of this little eminence is the opening of a minute sac—the utricle or sinus pocularis—which is thought to be the analogue of the uterine cavity in the female. Close to the edge of this sinus, and sometimes within it, are the orifices of the ejaculatory ducts. Along the sides of the verumontanum open the prostatic glands proper, to the number of from twenty to thirty.

The prostate is enclosed in a tough fibrous capsule which is a part of the pelvic fascia. Besides its attachments to the bladder and deep perineal fascia, it is further held anteriorly by the pubo-prostatic ligaments, and posteriorly by the recto-vesical fascia. Its slight mobility is provided for by the levatores prostatæ—muscular bundles, really parts of the levator ani—which, arising from the posterior surface of the pubes, are inserted along the lateral borders of the gland.

Its blood-supply is derived from the internal pudic, the vesical and hæmorrhoidal arteries, and the veins which form a plexus around the gland empty through the hypogastric vein. The nerves are branches of the hypogastric plexus of the sympathetic.

PHYSIOLOGY.—The prostate is a sexual gland. After birth it remains in a quiescent state up to puberty, when it begins to increase in size and development. It attains its full growth about the twenty-fifth year.

The secretion of the glands, which are especially active during sexual excitement, is a clear fluid of neutral reaction, with a specific gravity of 1.010.

It is especially rich in chloride of sodium (one per cent.) and as solutions of this salt are known to excite the spermatozoa to movement, its presence in the prostatic fluid is thought by some to perpetuate their activity. Probably the most important function of this secretion is, however, as a lubricant to the urethra.

The prostate, further, in its character as a muscular organ, acts as an involuntary sphincter of the bladder. As the urine accumulates a point is finally reached at which the tension of the detrusor urinæ muscle pulls open the rings of involuntary fibres around the neck of the bladder and allows the urine to enter the pars prostatica urethræ. Its presence there causes an urgent desire to urinate, and the escape of the water is then only prevented by the compressor urethræ muscle, which is the voluntary urinary sphincter. If this muscle does not relax and allow urination to be completed, the prostate closes down and forces the contained urine back into the bladder, where it stays until the further increased tension brings on another "besoin d'uriner."

Malformations.—The prostate may be wholly wanting,

in connection with a general lack of development of the urinary organs.

In exstrophy of the bladder there is no roof to the prostatic urethra, and the gland-ducts may be seen opening through the mucous membrane over the site of the organ.

Injuries and Wounds.—The deep-seated position of the prostate makes it little liable to injury from without. In severe crushes of the pelvis with fracture about the pubes, it may be wounded. In perineal lithotomy it is always incised, and often somewhat contused by the extraction of the stone. If the crushing and laceration of the parts have not been serious, healing usually takes place kindly.

Injury of the prostate occasionally results from the passage of instruments through the urethra. This occurs most commonly in cases of hypertrophy, where the irregular enlargement of parts of the gland has made the canal tortuous.

A specimen in the Museum of the Harvard Medical School, shows a very much enlarged middle lobe which so obstructed the entrance of the catheter, that the instrument had been forced directly through it and had entered the bladder beyond.

The knowledge that such injuries are possible should lead to their avoidance. Much force is never needed in the passage of an instrument which is properly guided; but a thorough understanding of the nature of the possible obstacles, and considerable patience and care in overcoming them, are necessary to success in these cases.

INFLAMMATION OF THE PROSTATE — PROSTATITIS — may be either acute or chronic.

Acute prostatitis is commonly the result of the extension of an inflammation from adjacent parts.

A gonorrhœal urethritis is by far the most usual exciting cause. In this case the inflammation runs back along the urethra to the prostate. That this is not the usual course of a gonorrhœa is due to the protection afforded by the constrictor urethræ muscle. This sphincter, surrounding the membranous urethra, prevents the discharge from penetrating to the prostate and bladder, and usually protects these deeper parts from participation in anterior inflammations. Occasionally the passage of an instrument, or the forcing of an injection through the constrictor, may convey infective discharges past this natural barrier.

A non-specific urethritis or an inflammation of the bladder may, in similar manner, extend to the prostate. Acute inflammation of this gland may also be excited by mechanical irritation. This may proceed from the passage of instruments, from the application of caustics, from the use of strong injections, from the presence of calculi in the bladder or prostate, from accidental injuries, or from operations.

Among other causes cited as occasionally giving rise to prostatitis, may be mentioned sexual abuses, acrid irritating conditions of the urine, the use of stimulating diuretics such as cantharides and turpentine, the abuse of stimulants, and the presence of inflammation in the rectum. Probably these conditions are rarely, if ever, competent to excite an acute prostatitis in a healthy state of the gland, but only act to aggravate an already existing inflammation.

A stricture of the urethra greatly aggravates any deep inflammation of that canal, and makes its extension to the prostate much more liable to occur.

Pathology. In acute inflammation the prostate is much congested, with great swelling and œdema, which extend to the surrounding parts. The prostate itself may be enlarged to three or four times its natural size, and even with this degree of inflammation, resolution and a return to a comparatively normal condition is possible.

If, however, the inflammation runs a more acute course, it may lead to the formation of abscesses, which, starting as minute points of pus, may gradually enlarge and coalesce until, in an extreme case, the whole organ may be reduced to one abscess-cavity.

Spontaneous opening may take place backward into the rectum, into the urethra, or bladder, and the pus may even occasionally find its way down through the ischio-rectal fossa, or into the perineum, and point externally. Rarely, the abscess may open into the peritoneal cavity, or into an adherent coil of intestine.

Symptomatology. The prominent symptoms are pain deep in the perineum and in the rectum, with tenesmus of the bladder and the rectum. Urination is very frequent, and is accompanied by great pain, especially during the passage of the last few drops of water, which are frequently colored with blood.

Accompanying these local symptoms, there is usually considerable fever, which may, or may not, be ushered in by a chill. There is, also, often severe pain in the back, loins, and thighs.

As the inflammation increases the pains become even more severe, the urine in its passage scalds intensely, the pressure and throbbing pain in the rectum become very distressing, and defecation, which is constantly desired, is, when it happens, a new source of suffering.

The stream of urine becomes small and hard to start, owing both to the swelling of the prostate and to the spasmodic contraction of the constrictor urethræ muscle, and finally complete retention may result.

If a gonorrhœal discharge previously existed, it may disappear at the onset of prostatic inflammation, or it may be changed into a slight mucous discharge.

There is usually a good deal of tenderness in the perineum, and sometimes also close above the symphysis pubis. A rectal examination is difficult on account of the extreme sensitiveness of the parts, accompanied by spasm of the sphincter muscle.

If the inflammation gives rise to an abscess, its formation is often heralded by rigors with high fever. If the abscess breaks into the urethra or bladder, there may be a sudden escape of pus in the urine, with an improvement of the general symptoms.

If the pus-cavity attains any considerable size, its character may be made out through the rectum, where it is to be felt, first as a hard, boggy swelling, which later softens and gives evidence of fluctuation.

If the abscess extends into the loose cellular tissue along the rectum, pyæmic symptoms may develop, and in case of rupture into the peritoneal cavity the characteristic symptoms of peritonitis will come on abruptly, with a speedily fatal issue.

Treatment. Absolute rest is the first and most important measure when acute inflammation of the prostate makes its appearance.

The patient should keep in a horizontal position with the hips somewhat raised.

If severe pain is present—especially if frequent spasms of the bladder are aggravating the inflamed gland—opiates should be given; and it is to be borne in mind that these, by inducing rest from spasm, exert a really curative effect. Morphia and atropia subcutaneously, or opium and belladonna suppositories, may be administered under these circumstances.

All irritations from instrumentation, injections, or stimulating diuretics, should be avoided.

The bowels should be kept gently open by aperients, if necessary, and this point should be carefully looked after when opiates are being used.

The urine should be rendered as unirritating as possible by the use of diluents and alkaline diuretics, and nourishment should be given in a bland, unstimulating form. Farinaceous gruels, milk, and light broths may form the bulk of the diet. Alcohol should be entirely avoided in the acute stage of the disease.

If at the outset the fever runs high, it may be somewhat mitigated by the use of quinine or some more temporary febrifuge, such as aconite or antipyrine. Late in the disease, when it has run a severe course—especially in case of exhausting suppuration—strong concentrated foods and alcoholic stimulants may be required.

Locally, all possible measures for limiting the severity of the inflammation should be employed. In an early stage of the disease, leeches applied to the perineum may be of considerable service. From six to eight should be

put on along the raphé and close to the anus. The bleeding may be encouraged, especially in plethoric persons, until from fourteen to sixteen ounces have been withdrawn.

Hot applications, either by fomentations or by hot water bottles, to the perineum and over the pubes, are useful in diminishing pain and spasm, and probably assist somewhat in lessening the inflammation. Hot hip-baths are recommended for this same purpose; but the exertion and the unfavorable position required for these, add so much to the pelvic congestion as to greatly diminish the otherwise favorable effect of the heat. If used, they should not be prolonged for more than five or eight minutes, as the maximum effect on the surface is produced in that time.

If retention of urine occurs, it must be relieved by the careful introduction of a small, soft catheter (Nos. 12 to 14 French scale).

Sometimes, when there is a spasmodic stricture at the compressor urethræ, a soft catheter will not pass, and a stiff instrument must be used, requiring, of course, the greatest gentleness of manipulation.*

When the retention persists and requires repeated catheterization, an instrument tied into the bladder (*sonde à demeure*) will often cause less irritation than would its frequent introduction.

The possibility of abscess formation is always to be kept in mind, and the condition of the gland should be watched by rectal examinations. If fluctuation is made out, the abscess should be opened at once. This may usually be done through the rectal wall with a curved *bistouri caché*, and the opening should be rather a puncture than a long incision. This is for the purpose of avoiding hæmorrhage; and it is a good plan, with this same object in view, to make a careful examination before the puncture, to see that no vessel of any size in the rectal wall stands in danger of injury by the knife. In case of bleeding, ice pellets should be introduced into the rectum, and if these fail, pressure should be applied by a thorough plugging of the lower part of the bowel.

If examination shows that the abscess is working toward the perineum, it may be opened by an incision from that direction, and thus a urethro-rectal fistula with prolonged suppuration may be avoided.

When the abscess communicates with the rectum thorough irrigation of the bowel should be carried out, and an antiseptic, free from poisonous properties, should be selected, on account of the absorptive power of the rectal mucous membrane.

If the disease ends in resolution, care should be taken that the recovery is complete, for an acute inflammation may, if neglected, leave a chronic condition which is sometimes extremely hard to relieve.

Chronic Prostatitis.—Chronic inflammation of the prostate may, as has been said, follow an acute attack. It may, however, on the other hand, originate as a chronic or subacute affection.

What has been said in regard to the etiology of acute, will for the most part apply to chronic, prostatitis; but while the former is seldom the result of sexual errors alone, these are not infrequently almost wholly responsible for a chronic inflammation of the gland; and it is to be noticed that the imperfect sexual indulgence of masturbation, or partial intercourse, is much more productive of prostatic trouble than is the normal excitement of proper coition. This is probably due to the unrelieved congestion of the gland, left after these unnatural practices.

Pathology. A chronically inflamed prostate is usually somewhat enlarged, but may be natural or diminished in size. The gland is less firm than in health, and its texture is more open and spongy. Upon section the cut surface is red or dusky in hue, and moister than normal. Little points of suppuration may exist, but are usually few and small.

The mucous membrane has an increased vascularity and may be thinned, particularly if the prostatic urethra is dilated in consequence of an anterior stricture. It may, on the other hand, be thick and spongy, denuded partly of epithelium, or much roughened with spots of ulceration. Sometimes, in cases of long standing, it is pigmented. The sinus pocularis and dilated gland-ducts about it may contain pus. Sometimes an abscess-cavity exists in communication with the urethra.

Symptomatology. Patients with chronic prostatic inflammation are troubled with increased frequency of micturition, which in a mild case may be scarcely noticeable, but is often very troublesome—occurring sometimes with intervals of less than an hour.

There is usually pain of a dull, heavy character, referred to the perineum and lower rectum. There may also be considerable pain low down in the back, with twinges shooting into the thighs and testicles.

The bladder, when full, may make its condition known by a feeling of discomfort or actual pain, with intensely urgent call to urinate.

The passage of urine may be accompanied by slight scalding sensations, and there may be a twinge at the end of micturition, when the bladder shuts down upon the sensitive prostate. Occasionally tenderness in the perineum may be felt upon deep pressure.

The urine is usually cloudy and contains, more or less abundantly, clumps of muco-pus mixed with epithelial cells. These are little accumulations of secretion washed out of the dilated gland-ducts, and differ from the loose threads of mucus so common in chronic urethritis in being smaller, more coherent, and rounded in form. When the urine is passed in two portions, the first part is apt to be more cloudy and to contain these clumps of mucus more abundantly than the second part. Not infrequently, however, even when the inflammation is confined to the prostate, the pus is distributed throughout the urine and both portions are cloudy. The reason for this has been very clearly stated by Ultzmann,* and is as follows: The internal sphincter of involuntary fibres surrounding the vesical orifice of the urethra is comparatively feeble, while the compressor urethræ muscle, just in front of the prostate and surrounding the membranous urethra, is strong and competent, and being under the control of the will, it forms the voluntary sphincter of the bladder.

As discharges collect in the prostate they cannot force their way forward past the constrictor, but readily escape backward into the bladder, where they diffuse themselves through the urine. Even in these cases, however, when the urine is universally cloudy, the first portion will still be somewhat more cloudy than that which follows, and will contain many more of the mucous prostatic clumps.

The urine, when examined microscopically, will often be found to contain, besides the pus, a considerable number of blood-cells, and occasionally also a few spermatozoa. The blood may not infrequently be perceived to come at the end of micturition, when the bladder closes down upon and squeezes the congested prostate.

A chemical examination frequently shows the presence of a little albumen, often in larger quantity than the pus and blood would account for. In other respects the urine is usually normal.

If the character of the stream is noticed, it will often be found that its force is decidedly diminished, and that after the completion of urination a few drops dribble away. Sometimes partial or total retention may occur.

This interference with urination is to be partly accounted for by the swelling of the prostatic mucous membrane, but is often largely dependent on a spasmodic contraction of the constrictor urethræ muscle; and if under these circumstances a sound is passed, it will meet with decided resistance when it reaches the voluntary sphincter.

This spasmodic stricture may be so close as to greatly aggravate the difficulty and pain of micturition, for, as the bladder forces the urine into the prostatic urethra, if

* For the discussion of catheterization see under Hypertrophy of the Prostate.

* Pyuria, p. 26.

its further escape is prevented, the undue pressure in this sensitive part is productive of very great suffering. Usually the spasm of the constrictor is finally overcome by the accumulating intra-vesical pressure, and urination, beginning first by drops, presently comes with more or less freedom.

As we have said, the constrictor muscle prevents prostatic secretions from escaping anteriorly and appearing as a urethral discharge. Not infrequently, however, in these cases a glairy discharge of prostatic mucus is pressed out and escapes while the patient is at stool; especially is this the case when the bowels are constipated and much straining is required. This is commonly interpreted by the patient as an escape of semen, and he becomes convinced that he is a victim of spermatorrhœa.

Usually the microscope fails to find spermatozoa in this discharge, which consists mainly of mucus, with sometimes a little admixture of pus and blood.

Besides the local symptoms and manifestations that have been described, we see in these prostatic cases often marked changes in the general condition of our patients. They are nervous and hysterical, or may be depressed and despondent, with often a hypochondriacal over-estimate of the gravity of their trouble. Sometimes a true neurasthenic condition may be induced in a case of long standing. Digestive disturbances and palpitation of the heart may occur.

Physical Signs. An examination of the prostate through the rectum shows it sometimes slightly enlarged, but often normal or diminished in size. In consistency it is usually somewhat softer than in health.

If the urethra is explored with an instrument it is commonly very sensitive, but may be anæsthetic; the latter condition being noticed usually in old cases. The urethra should be carefully examined for a possible stricture, and it is to be remembered that the constrictor muscle will be often found to make a spasmodic contraction just behind the triangular ligament. The passage of the sound through the prostatic urethra is almost always painful, and may excite an intense desire to urinate, or an ejaculation of semen.

Diagnosis. The disease which we are considering is peculiar to young and middle-aged men, and is to be kept distinctly separate from hypertrophy of the prostate, which only occurs in the old. Inflammatory symptoms, it is true, are not uncommon in this latter affection, and will be discussed later.

Tuberculosis of the prostate offers many points of resemblance to chronic prostatitis, and a differential diagnosis is often difficult, and may be for a time impossible. The constitutional tendencies of the patient should be taken into consideration, and a careful search should be made for evidences of tuberculosis in other organs. An examination of the urine for tubercle-bacilli may help to a solution, but a failure to find them even after careful search leaves the question where it was before, for they are often sought in vain in undoubted cases of genito-urinary tuberculosis.

The discrimination between prostatitis and deep urethritis after gonorrhœa, is sometimes almost impossible. The rectal examination of the prostate may help to a decision, but not infrequently gives negative results.

A microscopical examination of the discharge obtained by pressure on the prostate through the rectum may give valuable information, but this, too, is often misleading. The discharge in either case contains pus and large and small round epithelial cells. Amyloid bodies and cylinder or caudate epithelium may be found in considerable abundance when the discharge is prostatic.

The formation of Böttcher's crystals upon the addition of a drop of a one per cent. solution of phosphate of ammonia to a drop of the secretion, shows beyond question that it contains prostatic fluid.

This reaction should be conducted on a microscope slide, under a cover-glass, and within an hour, usually, crystals such as are shown in Fig. 3113 make their appearance. They are composed of a phosphate formed from a base which exists in prostatic fluid, and which is supposed to impart to it its peculiar odor. Unfortunately, the mixture of urine with the secretion prevents the formation of these crystals, and so limits very much their diagnostic usefulness.

It is always to be borne in mind that a combination of urethritis and prostatitis is not uncommon.

Treatment should be addressed to both the general and the local condition.

The general treatment should be tonic, especially in the cases where much nervous depression exists.

A generous, unstimulating diet, with moderate exercise in the open air, and with cold sponge-baths in the morning, when the patient's strength will admit of them, are to be advised.

The laws of sexual hygiene should be carefully explained to the patient, and the importance of their observance made plain to him.

Preparations of strychnine and iron are often of benefit, and they may be advantageously combined with quinine or ergot, both of which seem to exert a soothing influence upon the prostate. Iodide of potash may be of assistance when the inflammation affects the glandular portions of the organ, and the addition of bromide of potash is sometimes distinctly useful in quieting sexual excitement.

If the urine is highly acid or otherwise irritating, its

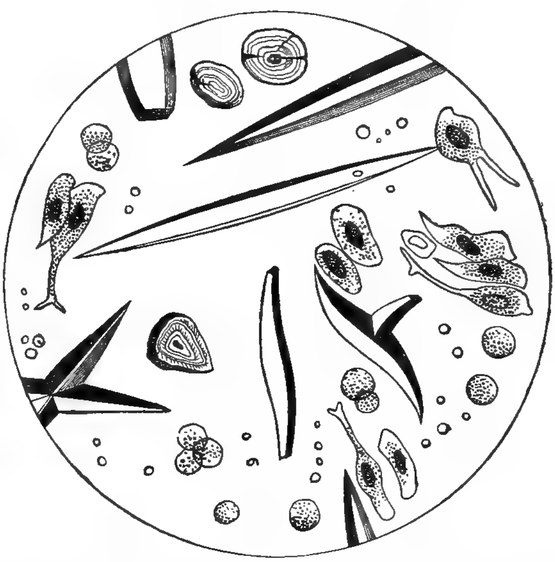

FIG. 3113.—Sediment from Prostatic Discharge, Containing Pus and Epithelial Cells, Granules, Amyloid Bodies, and Böttcher's Crystals.

character should be modified by demulcent drinks and by alkaline diuretics.

For a more direct local effect, cantharides, turpentine, sandal-wood oil, or copaiba may sometimes be administered with advantage, especially when the inflammation is mostly confined to the prostatic urethral mucous membrane.

Various local measures of treatment may be expected to contribute to the cure.

Counter-irritation to the perineum, either with tincture of iodine or with fly-blisters, is often of great use. Cantharidal collodion is a convenient blistering medium, and should be applied to a small surface close to the raphé.

Whatever counter-irritant is used, care should be taken that it does not come in contact with the scrotum or anus. After the application is dry, it is a good plan to fix a pad of absorbent cotton in the perineum with a T-bandage. This takes up the perspiration and prevents the blister from spreading to the side opposite to that where it was applied.

When there is much pain in the prostate and rectum, hot injections into the bowel may help to palliate it, and to reduce the congestion in the same manner that hot douches act upon the female pelvic organs.

FIG. 3114.—Urethral Suppositor. Consists of a hollow tube with a stylet for pushing in the suppository.

The most important local treatment, however, is that applied directly to the prostate itself, and consists in the passage of sounds, and in applications and injections into the prostatic urethra.

The use of sounds in chronic inflammation of the prostate has long been recognized as of advantage, and the benefit from them has been variously explained.

Some surgeons think that they should be used cold, and ascribe their efficiency to the astringent action of the cold. Others consider that their pressure within the prostate exerts some beneficial influence by pressing the blood out of the gland.

While some good may perhaps be attained in either or both of these ways, it is probable that the stretching of the constrictor urethræ muscle, and the consequent relief from spasmodic contraction of the same, will account, in a large measure, for the good results that follow their use. As has been said above, this sphincter is not infrequently put in a spasmodic state of contraction by the proximity of the prostatic inflammation, and in this state of stricture it has a tendency to aggravate the deep inflammation, just as an organic stricture tends to increase and perpetuate a urethritis posterior to it. It can be readily understood, therefore, that the relief of this spasmodic contraction would act favorably upon the inflammation behind it.

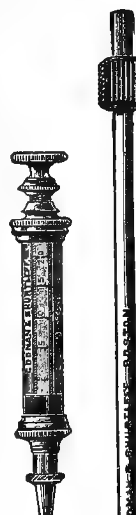

FIG. 3115.—Ultzman's Prostatic Syringe. A capillary tube and graduated syringe for the introduction of strong solutions. The curve of this and of the irrigating catheter is modified from Ultzman's instruments. See text.

As large a sound as will pass comfortably through the urethra should be used, and it should be introduced with the greatest gentleness. A sound passed roughly down through the anterior urethra will sometimes find the constrictor tightly closed against it, when, had more care been exercised the urethra would not have resented its introduction, and it would have readily passed the moderately contracted sphincter.

If the spasmodic stricture is a tight one, it will sometimes be found necessary to precede the introduction of the sound by the passage of a French, olive-pointed, conical bougie; which, insinuating its point through the obstruction, readily dilates it and prepares the way for the larger instrument.

When excessive irritability or an access of inflammation make the application of cold to the prostate desirable, it may best be accomplished by the use of the cold sound. This is a hollow instrument, which after its introduction can be chilled down by a stream of water through it. It should usually be kept in place for about five minutes.

We now come to speak of local applications to the prostatic urethra, and in these we recognize the most efficient means at our command for subduing chronic inflammation of this part.

The cases which are particularly suited to this form of treatment are those in which prostatic clumps are present in the urine, with or without a purulent secretion; in short, where the mucous membrane is distinctly affected. Medication may be conveyed to the pars prostatica urethræ either in the form of soluble bougies, by the injection of a few drops of a strong solution, or by irrigation with considerable quantities of a weak solution.

Soluble bougies are useful when it is desired to introduce an insoluble drug. They are made with gelatine or cocoa butter, in the shape of little rods about two inches in length, and are put in place with a urethral suppositor. Iodoform may be conveyed into the urethra in this way, and is often of considerable service in these cases.

The application of soluble drugs to the prostatic urethra is probably best accomplished by the injection of solutions.

The constrictor muscle, situated just before the prostate, prevents the penetration of an ordinary urethral injection, and special instruments are therefore needed for medication in the urethra posterior to it. Figs. 3115 and 3117 represent such catheters for prostatic medication.

The curve shown in these instruments has advantages both in the ease of introduction, and in the readiness with which the location of the point can be determined from the position of the handle. When the instrument is vertical* the point necessarily rests just in front of the triangular ligament; now, upon bringing it down to an angle of forty-five degrees, and at the same time advancing it slightly, the point slips through the constrictor muscle, but never passes beyond the prostate unless a special effort is made to push it on toward the bladder. Fluid injected through the catheter, when in this position, cannot pass forward through the constrictor, but washes out the prostate and escapes backward into the bladder.

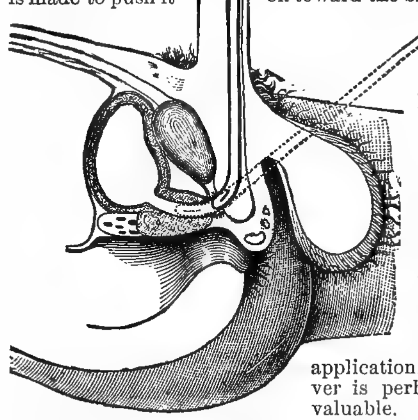

FIG. 3116.—Diagram showing that if a short-beaked instrument is held with the handle vertical, the point rests just at the triangular ligament. The dotted figure shows how the point slips through the constrictor muscle when the handle is brought to an angle of forty-five degrees with the axis of the body.

Of the various drugs used for prostatic application, nitrate of silver is perhaps the most valuable.

Two or three minims of a one to two per cent. solution should be thrown into the prostatic urethra through the capillary catheter (Fig. 3115).

Some pain of a burning character, with often considerable tenesmus, follows the application; but this usually passes off in the course of an hour or two. The injection should be repeated every four or five days, and its effect may sometimes be heightened by the previous passage of a sound. As convalescence is established, the intervals in the treatment should be gradually lengthened.

Irrigation of the prostatic urethra may often be practised with great benefit. In case there is much irritability of the neck of the bladder, with considerable muco-purulent secretion, a soothing antiseptic wash is of use. A two per cent. solution of borax or boracic acid, with the addition of a little glycerine, is a good injection for this purpose.

If the use of an astringent wash seems indicated, any of the mixtures useful in gonorrhœa may be tried. Perhaps a one per cent. solution of acetate of zinc is as good as any. The irrigating fluid, after washing out the prostate, flows back into the bladder, as has been said, and

* Throughout this article, when the manipulation of instruments is described, it is supposed that the patient is in a horizontal position.

from there it may either be withdrawn by slightly advancing the catheter, or it may be passed by the natural efforts.

After any manipulation or treatment of the prostatic urethra the patient should keep quiet, if possible recumbent, until all serious discomfort passes away, and should avoid any exposure to chill or fatigue for several hours.

Hypertrophy of the Prostate, Enlarged Prostate.—*Etiology.*—The causes of enlargement of the prostate are difficult to establish by any adequate proof.

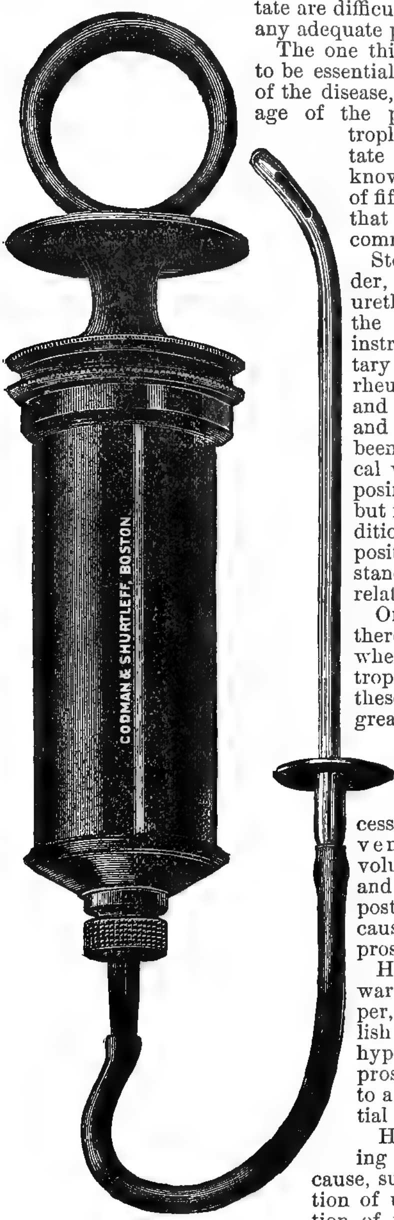

Fig. 3117.—Irrigating Catheter. (After Ultzman.)

The one thing which seems to be essential to the existence of the disease, is the advanced age of the patient. Hypertrophy of the prostate is practically unknown before the age of fifty, whereas after that it is extremely common.

Stone in the bladder, stricture of the urethra, irritation by the frequent use of instruments, sedentary habits, gouty or rheumatic diathesis, and exposure to cold and damp, have all been cited by surgical writers as predisposing circumstances; but none of these conditions has ever been positively shown to stand in a causative relation to the disease.

On the other hand, there is no doubt that, when prostatic hypertrophy exists, any of these conditions may greatly aggravate its symptoms; and besides those already named we may mention excesses in drink or in venery, prolonged voluntary retention, and the recumbent posture as familiar causes of increased prostatic congestion.

Harrison comes forward, in a recent paper, and tries to establish the position that hypertrophy of the prostate is secondary to a condition of partial retention.

He says: "Assuming that from any cause, such as long retention of urine, habit, position of the body, or the weakness connected with advancing years, the trigone, or non-contractile part of the bladder, becomes permanently depressed or altered in form, so that the person finds himself unable to get rid of the last half-ounce or so of urine, the effect will be frequently repeated efforts in all the muscles immediately adjacent to a part which, by reason of its connections and structure, has but little power of expelling.

"This will eventually lead, as I have shown, to the hypertrophy of the muscular fibres between the orifices of the ureters—the inter-uretal bar—as well as, I believe, to that of the muscular fibres so largely entering into the composition of the prostate. In this, I submit, will be found the immediate cause of prostatic hypertrophy."

It is difficult to see how, if we accept as true this theory of Mr. Harrison, we shall be able to explain the absence of prostatic hypertrophy in those cases of stricture, occurring in young or middle-aged men, where all of the expulsive muscular apparatus of the bladder is greatly hypertrophied, and still the prostate does not increase in size. This, too, at an age when the tendency to muscular hypertrophy is much greater than it is later in life. Mr. Harrison's theory also does not explain those cases of hypertrophy in which the hyperplasia affects mainly the glandular portions of the organ.

Pathology.—Hypertrophy of the prostate may occur through hyperplasia of the glandular portions of the organ, of the interstitial tissue, or of both.

As the normal size of a particular prostate can never be known, it may be hard to say, even on post-mortem examination, whether a given specimen is enlarged or not. For approximate determination, however, a prostate weighing six drachms may be regarded as normal in size, and anything over that is to be considered as hypertrophied.

Upon section of a prostate which is hypertrophied, the cut surface bulges irregularly above the capsule. It may be grayish-yellow in color or mottled with blotches of red, yellow, and gray, with occasional dark pigmented spots.

If the glandular element predominates the surface is soft, and exudes a fluid rich in cells. In interstitial hyperplasia the surface is dryer and firmer.

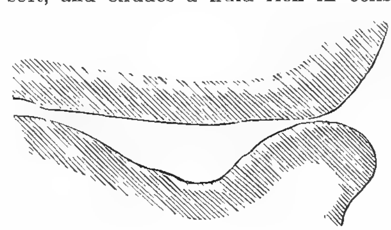

Fig. 3118.—Diagram to show the Shape of the Urethra in a Vertical Section through a Prostate with an Enlarged Middle Lobe.

Sometimes little projecting bunches announce the formation of fibrous or glandular tumors within the organ.

Usually the hypertrophy affects all parts of the gland simultaneously, but not all in the same degree.

The shape of the prostatic urethra—a matter of the first clinical and surgical importance—depends largely upon the partial or general character of the hypertrophy. If the enlargement is pretty evenly distributed throughout the organ, the urethra is in the first place considerably lengthened, sometimes measuring even seven centimetres. When the hypertrophy is partial the elongation is less, though it is still marked.

Furthermore, in cases of general hypertrophy, as the lateral lobes enlarge they compress the urethra from the sides, until it becomes a slit-like canal with tolerably firm walls in close apposition. As the lateral diameter is thus diminished, the antero-posterior diameter is correspondingly increased.

It will be readily seen that, as long as the enlargement is symmetrical, the direction of the urethra is not materially altered; but on the other hand, it is equally evident that if the hypertrophy is partial, and not evenly distributed, the unequal pressure from one side or the other of the canal will cause lateral deviations, and that, if the middle lobe is unduly enlarged, the posterior portion of the urethral floor will be raised, causing a deviation upward or toward the pubes (see Fig. 3118).

The projection upward of this lobe may make the internal urethral opening crescentic in shape, and if the middle coalesces with either of the lateral lobes this orifice is pushed over toward the opposite side.

Sometimes the middle lobe grows out into the bladder as a distinct tumor, which may be attached by a broad base, or may stand off in a pedunculated polypoid form.

Besides the changes in the prostate itself, there are

other alterations in associated organs which we must consider in connection with this disease, as they are instrumental in producing many of the symptoms which we shall have to study.

As the prostate enlarges the internal meatus is raised and a pocket is formed in the bladder just behind the enlarged gland. The bladder-wall also becomes thickened, partly in consequence of hypertrophy of the muscular coat, owing to the increased resistance against which it has to work, and partly owing to a sclerosis of the interstitial fibrous tissue, like that which has occurred in the prostate.

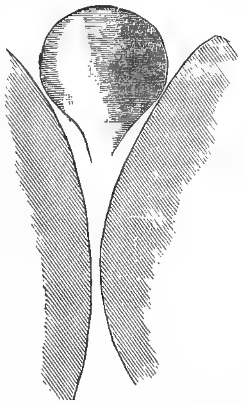

FIG. 3119.—Diagram of a Horizontal Section through the same Organ, showing how the urethra divides and goes on either side of the middle lobe.

Interlacing muscular bands often stand out from the vesical wall under these circumstances, forming trabeculæ between which there are, not infrequently, considerable pouches of mucous membrane.

The walls of the ureters and pelves of the kidneys may also be somewhat thickened, and the interstitial renal tissue undergoes frequently a hyperplasia.

As a later result of the prostatic obstruction the bladder, ureters, and pelves of the kidneys may become greatly distended.

Guyon and Lannois have laid particular stress upon the fact, already hinted at and partly understood by earlier writers, that, coincident with these changes in the urinary tract, a general sclerosis, affecting specially the walls of the blood-vessels, is going on throughout the body.

When from any cause inflammation of the bladder, ureters, or kidneys has associated itself with hypertrophy of the prostate, we have the familiar pathological appearances of cystitis, pyelitis, and pyelo-nephritis engrafted upon the organs already seriously altered by the prostatic obstruction.

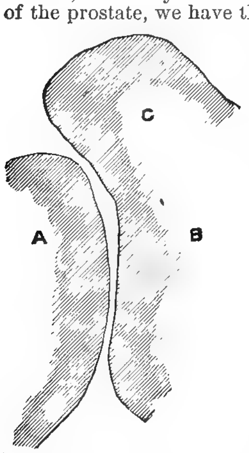

FIG. 3120.—Diagram of a Horizontal Section through a Prostate in which the right lobe, A, is moderately enlarged, the left lobe, B, somewhat less so, while the middle lobe, C, is much enlarged and is joined to the left lobe, causing a deviation of the vesical end of the urethra to the right.

For a full consideration of these complications see under Bladder and Kidneys in this HANDBOOK.

Natural History.—The progress of the disease is slow. The organs affected are not of vital importance, and the changes in them may reach a very advanced state before they seriously threaten life.

Guyon has divided the history of the disease into three periods: *First,* that of congestion, affecting mainly the prostate, but also in less degree the bladder and kidneys. *Secondly,* that of partial retention of urine. And, *thirdly,* that of distention of the bladder with usually secondary changes in the kidneys.

This somewhat empirical division gives us perhaps as good a framework as any for the classification of the clinical phenomena.

In the first stage, that of congestion, we have some enlargement of the prostate and functional disturbances, especially in the matter of urination. This condition may persist for a long time, and in certain cases, where for any reason the calibre of the urethra is not greatly interfered with, it may exist almost indefinitely without showing any tendency to pass on to the second stage, that of retention.

Usually, however, sooner or later the obstruction to the passage of the urine becomes greater than the force of the bladder can overcome, and a state of habitual partial retention is the result.

When this condition comes on slowly the accumulation of residual urine may be very insidious, and escape the observation of patient and physician alike; on the other hand, an increase in the prostatic obstruction may occur suddenly, and the unexpected complete stoppage of the urine may be the first announcement of trouble.

When the retention of the second stage of the disease develops gradually, and is not discovered and treated, the point may be finally reached where the bladder has completely lost its tone and is so distended, that the urine escapes almost constantly by an overflow (retention with incontinence). This same condition of things may follow also an acute retention which has not been relieved by catheterization and in which nature has finally established a leakage.

The third stage of the disease is now entered upon, and if nothing is done for such a case the distention of the bladder becomes extreme, and a secondary dilatation of the ureters and of the pelves of the kidneys takes place. This is soon followed by atrophy of the secreting portion of the kidney, and an increase of its interstitial tissue (interstitial nephritis).

The secondary changes in the heart and blood-vessels, usually associated with chronic nephritis, are likely to make themselves noticed at this time, if they have not already done so, and the disease becomes a constant and serious menace to life.

It is in this advanced stage of the disease that inflammatory processes, starting in the bladder, rapidly extend backward to the kidneys, and uræmic symptoms presently usher in the closing scene.

Symptomatology.—From what has been said in regard to the history and progress of the disease, it will be seen that the symptoms of the first stage are mainly dependent upon the condition of congestion in the prostate, bladder, and kidneys. And as this congestion is most considerable in the prostate, the most noticeable symptoms caused by it are disturbances of micturition and of sensation, due to the irritated state of the neck of the bladder.

In the second and third stages we have, in addition, a series of symptoms due to the mechanical obstruction to micturition, and to the changes in the bladder and other organs consequent upon this obstruction.

We shall have finally to consider the symptoms arising from various morbid conditions likely to appear as complications in the course of prostatic disease.

The first appearance of symptoms usually announces a morbid condition which has already been coming on for some time. When the enlargement takes place in such direction as not to encroach seriously on the calibre of the urethra, it may reach very considerable proportions before it causes any inconvenience to the patient.

One of the first symptoms to be noticed is an increased frequency of micturition, which is especially marked at night or early in the morning. Guyon regards this as evidence of congestion, which is aggravated during recumbency and sleep. He calls attention, also, to the frequent existence of erections in these patients, on waking, as further evidence of an increased congestion of the prostate during sleep.

Pain is ordinarily not very noticeable in the early stages of the disease, although a dull aching, or heavy dragging, sensation in the perineum, rectum, and behind the pubes is not uncommon.

If attention is paid to the manner in which urination is accomplished, it will be found that early in the disease the stream is slow to start and diminished in force. This is due largely to a loss of power in the bladder, but is to be partly explained by the swelling in the prostate, and by a spasmodic contraction and stammering action of the constrictor muscle.

The diminution in the force of the stream in a prostatic patient differs from that seen in cases of stricture,

in that, while a strictured patient can, by voluntary effort, increase the force of his stream, a man with enlarged prostate cannot do so.

Second Period. The symptoms which have their origin in congestion continue during this period, and are, indeed, intensified. Added to them we have other symptoms due to the retention, which is the characteristic condition of this stage of the disease.

The retention may be complete or incomplete.

Complete retention may be acute and appear suddenly, or it may be preceded by a period of partial retention which always develops slowly.

The symptoms which accompany a complete retention are easy of recognition, and a physical examination reveals the bladder distended above the pubes. Incomplete retention, on the other hand, comes on very insidiously, and is often overlooked for a long period, at just the time when recognition and treatment of the condition are of great importance.

Although, as has been said, partial retention comes on quietly, still a careful examination of the symptoms will usually elicit evidence of a changed condition of things, at or soon after the time when the bladder begins to fail of emptying itself. The feeling of weight behind the pubes is likely to be increased, and the frequency of micturition, which during the first stage was decidedly more pronounced at night, begins to be almost equally noticed in the daytime. The intervals between the acts of urination become short, and the call is imperative. In short, the bladder being always partly full, it takes but a small additional quantity to distend it to its full capacity.

The only positive means of determining the condition of the bladder is by a physical examination, and this should be made in every doubtful case.

Sometimes the bladder shows extraordinary tolerance, and the distention becomes so extreme as to cause incontinence from overflow, before the patient feels obliged to call upon a physician; and sometimes also, unfortunately, before the medical attendant recognizes the nature of the difficulty.

This incontinence is evidence of a very great degree of distention, and shows that the disease has entered upon its third stage. Usually, before it appears, the disease has already extended backward and has begun to affect the kidneys.

There is one symptom which may appear and give evidence that the disease has reached the third stage, before incontinence begins. This is polyuria. If the quantity of urine in the twenty-four hours is measured, it will be found to considerably exceed the normal.

Pain, which was an insignificant symptom in the first stage, may assume considerable importance in the second and third stages.

Besides the discomfort in the perineum and back due to the congested and irritated prostate, there is also considerable pain before and during micturition, caused by the distention of the bladder and its unavailing or partially successful attempts to empty itself. The passage of the urine through the prostate is also sometimes painful, and this is especially the case where the occurrence of inflammation has rendered the urine pungently alkaline and has made the parts particularly sensitive.

The examination of the urine may give negative results during the early stages of prostatic disease; but when the congestion of the kidneys is considerable there may be albumen, and even a few casts. During the last stage of the disease, when polyuria has established itself, the specific gravity is low (1.003 to 1.006) and there may be a small amount of albumen, although this is often not present. A few casts may be found at this time, too, but they are often absent even when the kidneys are extensively diseased.

In the presence of inflammatory complications the character of the urine is greatly changed, as we shall see later.

In addition to the more local symptoms which we have been considering, there are also certain general disturbances which are likely to appear in advanced prostatic disease. These are of two kinds, digestive and febrile.

Obstinate indigestion in an old man, especially if accompanied by nausea, should always lead us to take the condition of the prostate into consideration. These patients are also very liable to a low feverish condition, with extremely dry mouth and tongue, and this may announce the extension of inflammation from the bladder back into the kidneys.

We now come to the consideration of the complications which are likely to arise in prostatic cases, and of the symptoms, or variation in symptoms, to which they give rise.

They are cystitis, pyelitis (pyelo-nephritis), hæmaturia, and stone in the bladder.

Cystitis is so common in prostatic hypertrophy that it may be looked upon almost as a necessary result. It sometimes appears without apparent cause, sometimes in consequence of excesses in drink, or from exposure to cold. Far more commonly, however, it follows as a consequence of the use of the catheter or other instrument, and when it is once established it is rarely got rid of—but may, as we shall see, by appropriate treatment, be kept within very reasonable bounds.

When the inflammation of the bladder is at all acute, the pain and frequency of micturition are greatly increased. If the prostate shares in the inflammation, a great weight and bearing-down pain in the rectum may be felt, with a frequent urgent desire for defecation.

The urine becomes thick from the admixture of pus and mucus, which often settles at the bottom of the vessel in a thick, ropy mass. Presently, in the majority of cases, it undergoes alkaline fermentation, becomes ammoniacal, and has a strong pungent, often fetid, odor. The sediment now contains, besides the pus, abundant crystals of triple phosphates, often associated with finely granular amorphous phosphates.

If the inflammation extends from the bladder back through the ureters to the kidneys, the resulting pyelitis or pyelo-nephritis makes itself known by pain in the back, high fever, more or less diminution or even suppression of urine, and uræmic symptoms.

This course of things is especially liable to occur late in the disease, when neglect of catheterization has allowed the ureters to become greatly distended. Under these circumstances, any exposure to cold or instrumentation may be sufficient to start the fatal access of inflammation.

Occasionally, when the use of the catheter has been neglected after the time when it should have been begun, the final entrance upon the catheter life, instead of being a conservative measure, gives the final push toward a fatal issue. The existence of polyuria, with urine of a low specific gravity, should always lead us to fear this result.

Stone in the bladder not infrequently occurs in prostatic patients as a consequence of cystitis, in which case the stone is of the soft phosphatic variety; or a stone composed of uric acid, oxalate of lime, or cystin may form, and owe its origin primarily to a constitutional condition.

In either case the prostatic hypertrophy may be regarded as partly responsible for the formation of the calculus.

In the first case, of the phosphatic stone, the obstruction, by causing the cystitis and fermentation of the urine, stands in a pretty close causative relation to the calculus. In the second case, in which the deposit of crystals from the urine is due to a constitutional tendency, the obstruction at the prostate may be the condition which decides whether a stone shall form or not. For, when the bladder is completely emptied at each urination, the crystals as they form are thrown out and do no harm, whereas when a pocket has been formed behind the prostate in which there is always residual urine, the sand collects there and soon agglomerates itself into a concretion.

When a stone forms behind an enlarged prostate the pain is usually much increased, and is less amenable to treatment. It is referred often to the glans penis, and is

greatly aggravated by motion, especially by riding in a jolting vehicle. It is commonly less marked at night or during rest.

Hæmaturia in case of stone is very likely to appear after exercise or riding, while prostatic hæmorrhage from congestion seems to be independent of any jarring of the bladder—in fact, is rather more likely to come at night, when recumbency favors prostatic congestion.

The sudden stoppage of the stream in the midst of urination, by the rolling of the stone against the opening of the urethra, is less likely to occur in case of an enlarged prostate than in a healthy bladder, owing to the lodgement of the stone behind the prostate, below the urethral orifice.

If the presence of the stone affects the frequency of micturition, it tends to increase it rather in the daytime, when motion causes the stone to move about, than at night, when it is at rest.

Hæmaturia, as has been said, may result from the congestion of the prostate or from the presence of a stone. We may also have hæmorrhage of considerable amount and duration, following the use of instruments; and, lastly, the too sudden emptying of an over-distended bladder may lead to an attack of hæmaturia, from the capillary oozing from the vesical wall.

Sometimes clots of large size may form in the bladder, and cause much pain and discomfort before they are broken up and expelled.

Physical Examination.—Having decided from the symptoms that there is a probability that prostatic hypertrophy exists, a thorough examination should be made of the prostate and bladder.

The objects of this investigation are, to ascertain the stage at which the disease has arrived, to learn the amount of obstruction and the configuration of the prostatic urethra, and to discover any complicating conditions which may exist.

The patient should first empty the bladder, so far as possible by the natural efforts, and the hypogastrium should then be explored by palpation and percussion, to see whether enough distention of the bladder remains to be detected in this region. The normal variations in the position of the bladder and intestines render this examination often unsatisfactory, especially when the abdominal wall is thick or rigid.

The examiner should then explore with the forefinger the rectum. This is best done with the patient on the back.

If the prostate is enlarged it will be felt pressing down the anterior rectal wall. Its size, shape, and consistency should be noticed.

The relative enlargement of the lateral lobes can usually be well made out, and nodular projections are sometimes felt, caused by irregularities in the hypertrophy of different parts of the gland. Rectal examination, unfortunately, gives little or no information in regard to the condition of the third lobe, which is so often the cause of a serious obstruction to the flow of urine.

Incidentally the degree of tenderness to palpation will be discovered.

The condition of the prostate itself having been determined, the examining finger should be carried up along the posterior vesical wall, if that be possible, and the condition of the bladder should be learned. In this investigation the bi-manual manipulation between the finger in the rectum and the hand above the pubes, so commonly practised in examinations of the female pelvic organs, is useful, and by it the amount of distention of the bladder can often be most accurately made out.

Lastly, the urethra and bladder should be explored.

The existence of a stricture will probably be detected in the passage of instruments for deeper exploration. But in case of doubt the canal may be thoroughly examined with large bulbs. A short-beaked sound should be passed, and as it runs through the prostate deviations of the urethra will often be shown, by the feeling of resistance on one side or the other and by the turning of the handle.

The sound in entering the bladder may sometimes be felt to slip up over a bar, or may turn to one side around a prominent third lobe.

After a proper search has been made for a possible stone, the sound should be depressed until it lies in the axis of the body, and then withdrawn until the concave side of the beak comes against the neck of the bladder; it may then be rotated, and, as the beak sweeps the vesical face of the prostate, any irregular outgrowths or projections will be felt to arrest its movements.

If the sound has been felt to ride over an obstruction at the neck of the bladder and, after it is in, rotates firmly, this points to a bar rather than to a globular enlargement of the third lobe, which last would arrest the beak of the sound in rotation.

As the instrument is withdrawn slowly through the prostate, the deviations due to projections into the urethra are often felt even more plainly than during introduction.

Finally, the urine may be withdrawn with a catheter and the exact amount of residuum thus discovered. This will be found to vary much at different times, and depends somewhat upon the amount of urine which the bladder contained before the last urination.

When the bladder is full and the urine consequently rushes out with some force in a considerable stream, it will often be found that there is much less water left in the bladder than is the case when urination has been attempted before complete distention has been reached.

Diagnosis.—The conditions with which enlarged prostate is likely to be confounded are stricture of the urethra, stone in the bladder, cystitis, cancer or other tumor of the prostate, tuberculosis of the prostate, and tumor of the bladder.

The physical examination, if thoroughly made, usually enables us to eliminate the first two of these conditions, and if enlargement of the prostate with residual urine is found we may, in the absence of other discoverable cause, decide an existing cystitis to be dependent upon the prostatic trouble.

The decision between a tumor of the prostate and simple enlargement is extremely difficult, unless the tumor has assumed considerable proportions or has begun to invade surrounding parts. The physical examination by the rectum gives us our best help in diagnosis, but the irregular growth of a tumor may at first simulate the irregularities sometimes seen in hypertrophy.

The pain attendant upon the growth of a tumor is more severe than that appearing early in hypertrophy, though this is by no means constant.

In case of a cancer the enlargement of neighboring glands may help us to the right solution of the question. Not infrequently, however, it will be necessary to wait until the progressive growth of the tumor declares its character.

Tuberculosis of the prostate usually occurs earlier in life than we could look for hypertrophy. In case of doubt, tuberculous deposits must be sought for in other organs (epididymis, seminal vesicles, lungs, etc.).

A tumor of the bladder may give rise to hæmorrhages and difficulties of micturition which simulate those caused by enlargement of the prostate. Also a tumor may be present in the bladder behind an enlarged prostate, and so complicate the symptoms.

The hæmorrhage from a tumor is ordinarily very much greater than that from a congested prostate. But this is not always the case, and whenever there is persistent or intermittent hæmaturia, however slight, a careful search should be made for villi or other bits of the tumor which may be detached and passed in the urine, and which may be recognized under the microscope.

Examination of the bladder with the sound may, when a tumor is there, reveal a projection somewhere from its wall. But sensations of this sort are very misleading, and it is well, after a thorough sounding, to wash out the bladder with the litholapaxy evacuator, with the object of obtaining bits of the tumor, if one is there.

After definitely settling the diagnosis of prostatic hypertrophy, it is always important to go further, and to decide in what stage the disease is, as we shall see that the treatment should vary according to the varying conditions.

The steps to this decision have been sufficiently indicated above.

Treatment.—As has been described, the disease under consideration consists essentially in a tendency to congestion of the prostate, bladder, and kidneys, with an accompanying hypertrophy and sclerosis.

For convenience we have divided it into three stages: first, of congestion, with functional disturbances; second, of simple retention; and, third, of retention with distention, often incontinence, and perhaps involvement of the kidneys.

First we will consider those measures of treatment, hygienic and medical, which are applicable to all stages of the disease.

Anything which has a tendency to increase the congestion, should be carefully avoided. A chill of the surface should be especially guarded against. The patient should wear flannels next the skin, and should carefully avoid draughts or long exposure to chilly and damp air.

The feet should be kept dry and warm, and if the patient gets up at night to pass water, use the catheter, or for other purpose, he should cover his feet and legs warmly. Neglect of these precautions may at any time bring on an attack of retention, cystitis, or even of pyelo-nephritis.

Excesses in eating and drinking are to be avoided. Large quantities of rich or highly seasoned food must not be indulged in, and wine or beer are for the most part better left alone. This caution should be understood to apply only to overeating, as a sufficient quantity of nourishing food is of importance. If the patient has been in the habit of taking a stimulant, a little light claret, or some whiskey and water, may be allowed with meals.

Especial warning should be given against holding the water over the ordinary time, particularly if any call to pass it is felt. An attack of complete retention or of cystitis may result from disregard of this rule.

Venereal excesses are, of course, to be avoided.

The effect of sedentary habits and of horizontal decubitus in increasing the passive congestion, must be borne in mind, and moderate gentle exercise is to be advised. The patient will do well, when engaged in any occupation that keeps him long in one position, to take an occasional turn through the room; and at night or in the morning, when up for the purpose of emptying his bladder, a short walk about his chamber will often materially assist him in making his urination thorough and satisfactory.

Constipation should be carefully guarded against. In prescribing for this condition, the violently acting drugs, which produce more or less congestion of the pelvic organs, should not be used.

The greatest assistance will often be obtained from rectal injections. These are especially useful when the mechanical obstruction of the prostate, pressing upon the rectum, is largely responsible for the failure of the bowels to act.

Cold injections are usually to be avoided, though they may sometimes render good service in helping to restore the functions of an atonic bladder. Hot injections (112° to 115° F.) will sometimes assist in reducing congestion.

The functions of the skin should be stimulated as far as possible. Rubbing and massage are to be employed to this end, and baths also serve a useful purpose if care is taken against a subsequent chill. A hot bath ending with a sponge off in cold water, and vigorous friction with a rough towel, may be of real benefit, by bringing the blood to the skin and so relieving internal congestion.

In selecting a climate for a prostatic patient, preference should be given to dry inland localities, where sudden changes of temperature are less likely to occur than on the sea-coast. Sometimes, however, when the general condition is depressed and a stimulating climate is desirable, the sea-side may be tried, special precautions being taken against surface chills.

General medication directed against the disease itself has but little to offer.

The iodides may have a trial, in virtue of their reputation in the treatment of sclerotic conditions of the blood-vessels and other organs. If used they should be persisted in for a long time, with occasional intermissions. They have the disadvantage of sometimes disagreeing with the stomach, and it may be necessary to discontinue them on this account.

Of the medication required in the various morbid conditions which may from time to time need correction, we shall speak in considering the treatment of the various periods.

Treatment in the First Period is almost wholly hygienic and medical.

In the absence of complications, and before there is any retention, the less instrumentation the better, as it only aggravates the congestion, and introduces the danger of infection from dirty instruments.

If the urine is irritating from too great acidity, an alkaline diuretic, such as citrate or acetate of potash, is indicated.

In case of pain, belladonna or hyoscyamus should be administered either by the mouth or by the rectum. Opiates should be avoided, if possible, as they derange the stomach and constipate the bowels. When urgently required, however, they may occasionally be resorted to.

Ergot, strychnia, or nux vomica in some form, and quinine, are sometimes useful, and act apparently by diminishing the congestion, and perhaps also by stimulating the contractions of the bladder. If the circulation is not good, cardiac stimulants may be of assistance.

Second Period. When the stage of partial retention has set in and the patient passes water, but is not able to completely empty the bladder, it is necessary to resort to the use of the catheter. So important is this, that every patient who is seen in the first stage and put upon general treatment, should be warned that the time will almost certainly come when catheterization will be required, and that as there is no sure means by which he can tell when he reaches this state, he should occasionally present himself for examination to decide this point.

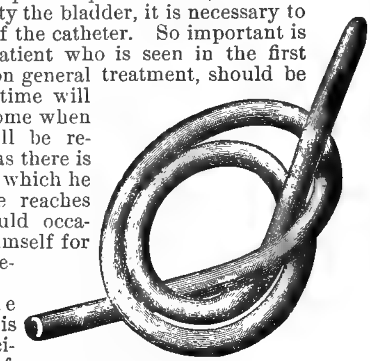

Fig. 3121.—Soft-rubber Catheter.

Sometimes the partial retention is due to some accidental increase of congestion, which may disappear under the use of antiphlogistics. In such a case the patient may be put to bed with leeches to the perineum, followed by hot applications assisted by opiates, if necessary.

If these measures fail, it will be necessary to draw the water, and it will sometimes be found that, after a short systematic use of the catheter, the bladder will recover itself and again become able to fully expel its contents. Thus the disease may occasionally be moved back from the second period into the first.

When complete retention comes on suddenly the catheter is indispensable, but in this case again its use may perhaps later be given up.

When entering upon the use of the catheter, we may often learn whether it is really needed by noticing the effect upon the symptoms. If these are relieved or ameliorated, we are evidently on the right track.

It is to be remembered, however, that not infrequently, on commencing catheterization, a cystitis develops itself, owing either to the too sudden evacuation of a distended bladder, to the introduction of dirt upon the catheter, or simply to the irritation from the constant use of instruments. It is important that the aggravation of symptoms caused by this inflammatory onset shall not lead the patient or doctor to infer that the catheter is doing harm and should be given up, for it is by continuing its use that the attack of cystitis may be most quickly and surely relieved.

Let us now consider how and with what instruments the catheterization is to be carried out.

As has been described, the walls of the urethra are pressed together and may be somewhat deviated by the inequalities of the lateral lobes. The posterior part of the urethral floor is also often raised by the projection of the third lobe.

Our object is to reach the bladder through this sinuous passage with the least possible amount of irritation.

FIG. 3122.—Elbowed Catheter (Sonde Coudée of Mercier).

If a soft, red rubber catheter will find its way into the bladder, it is, by all odds, the best instrument to use. It requires no skill for its direction, and can do no damage to the urethral walls—a point of great importance, as it enables us to entrust its use to an unskilful patient.

When, owing to the narrowness or tortuousness of the urethra, the rubber catheter will not pass, we must resort to a stiffer instrument, and must adapt its form in reference to the difficulties which it has to overcome.

The obstructions which it will meet project from the lateral walls and floor of the canal, and our effort must

FIG. 3123.—Double Elbowed Catheter (Sonde Bicoudée).

be to carry the point of the instrument along the upper or anterior wall.

Mercier devised for this purpose a flexible webbing catheter with the point sharply turned up (sonde coudée), so that it might ride over the obstructions on the floor.

For those cases in which the hypertrophy of the third lobe was very pronounced, he used a catheter with a second bend, designed to lift its point still higher.

In introducing these instruments, care should be taken that the point be kept turned toward the roof of the canal, and after it has passed the triangular ligament the penis should be depressed as much as possible between the thighs, so that the catheter may be pushed straight upward in the axis of the body.

The English gum-elastic catheter may often be used with advantage, either with or without its wire stylet. If introduced without a stylet it is a good plan to exaggerate the curve of the instrument, as has been suggested by Thompson. When used thus it should be introduced cold and carried as rapidly as possible through the anterior urethra, for as it warms it becomes flexible and loses its form. By passing it rapidly but carefully, its curve often carries it over the obstructing third lobe.

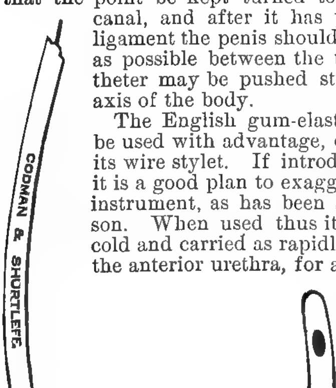

FIG. 3124.—English Gum-elastic Catheter with Exaggerated Curve on Stylet. (After Thompson.)

If it meets an obstruction and, warming in the urethra, becomes flexible, the forefinger in the rectum should be used to lift the point of the catheter into the prostate, while at the same time the handle should be brought down to the axis of the body, and the instrument, which is then practically straight, should be pushed steadily into the bladder. This should be done without the exercise of much force, as the point, when properly guided, slips along quite easily and when it catches there is danger of its making a false passage if pushed.

If the gum-elastic catheter is introduced with a stylet it should be curved into the form of a prostatic silver catheter. Sometimes, when the point catches it may be lifted over the obstruction by the simple manœuvre of slowly withdrawing the wire while slightly advancing the instrument. This curls the point upward and often enables it to ride over the obstacle.

Occasionally, when other flexible instruments fail, the French conical bougie catheter will succeed in worming its way through the canal. It should be used with great caution, as its comparatively sharp point may catch in and perforate the mucous membrane.

Failing with other instruments, we may have recourse to a metallic catheter of large curve.

The beak of this instrument should be long enough to reach easily through the enlarged prostate, which may be one inch and a half longer than in the normal state. If the curve is too short the point does not reach the bladder, but being engaged in the prostate, runs considerable risk of making a false passage when the handle of the instrument is depressed.

The forefinger in the rectum may give great assistance in guiding the passage of this catheter.

In using any instrument in a urethra with false passages it is a good plan to always withdraw for a considerable distance when the point is caught, and then to try and pass the pocket by carrying the beak down first one wall and then another until the right passage is found. Ordinarily the false passages exist in the floor of the urethra; but this rule has many exceptions.

If, in a case of complete retention, after careful and thorough attempts we do not succeed in reaching the bladder, recourse must be had to puncture with trocar or aspirating needle.

This was formerly done through the rectum with curved trocar, but as this method cannot be used antiseptically the supra-pubic puncture is to be preferred. This may be done with a fine needle introduced close above the pubes, and, if necessary, may be repeated two or three times daily for a considerable time. Usually, however, drawing off the urine in this way is followed by such a subsidence of the swelling as to presently allow the introduction of the catheter. Leeching the perineum and the administration of ergot may also be of service in reducing the congestion.

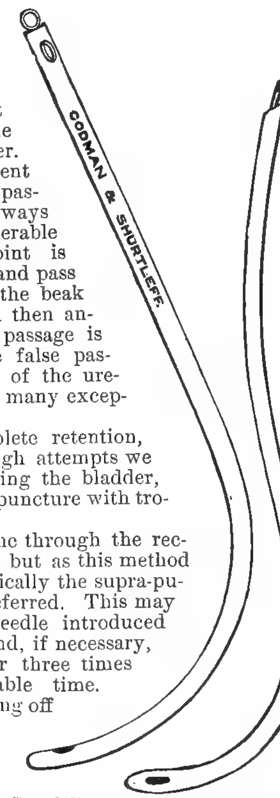

FIG. 3125.—Silver Catheters of Curve Appropriate for Use through an Enlarged Prostate.

The evacuation of a distended bladder, whether by catheter or by aspiration, should be performed slowly and carefully. When the distention is extreme, the bladder should not be wholly emptied at one time, for if the internal pressure is too suddenly relieved we are likely to have a great congestion of the vesical mucous membrane, with the escape of blood into the urine, followed often by considerable inflammation.

The greatest care should likewise be taken in the matter of thorough antiseptic cleanliness, as the introduction of germs into the bladder may start a fermentation of the urine with cystitis. It is of course important, whenever a catheter is entrusted to a patient, that careful instructions should be given to him in regard to this.

Catheterization having been commenced, how often should it be repeated?

In the cases of partial retention with moderate residu-

um, the use of the catheter each night before retiring is usually sufficient. As the disease progresses, however, a point is presently reached when the bladder habitually holds from six to eight ounces of residual urine, and the calls to urinate are consequently pretty frequent. Under these circumstances the regular use of the catheter is required.

If now the patient can get along comfortably while using the catheter four times a day, he is fortunate, and may live for twenty or more years with this artificial urination. Not infrequently catheterization will be required six, seven, or even more times in the twenty-four hours. Especially is this the case when cystitis is present. The water should always be drawn when the desire to micturate is urgent and persistent.

When catheterization is required so often as to become a decided source of irritation, and if the bladder is so irritable as to be constantly liable to painful contractions, it will be found best to tie in the catheter for a time (sonde à demeure). Usually in a few days, after the bladder has had a rest, the catheter can be again left out and the patient can resume regular catheterization.

Treatment of the Third Period. In this stage of the disease, systematic emptying of the bladder is as urgently called for as at any earlier time. The serious changes, however, which are likely to have occurred in the ureters and kidneys, with the condition of passive congestion which exists throughout the urinary tract, make the use of the catheter a matter of considerable danger, which, in some cases, may be so great that it will be better practice to leave the bladder undisturbed.

In these cases the patient's condition of comparative health—troubled, it is true, by frequent and often partly involuntary micturition, but not debarred from ordinary occupations—makes a striking contrast with the state of things which may rapidly develop upon entering on the "catheter life." For a slight added irritation to the bladder may be suddenly followed by a pyelo-nephritis, or even more abruptly by renal congestion with suppression, uræmia, and death.

These dangers are alarming and imminent enough to make us hesitate, but what is to be hoped from allowing the disease to take its course? Nothing but a certainly fatal issue, which is likely to come in a few weeks or months, and which may be precipitated at any time by an exposure to cold, by fatigue, or by a slight indiscretion in diet.

On the other hand, when catheterization is successfully established, the disease may be moved back from the third to the second stage, and the patient who was in such danger may be put in a state of comparative security.

It is, then, of the first importance to distinguish the cases in which catheterization is so dangerous that the patient had better be left to follow out the natural course of the disease; and in all except these most advanced cases the catheter should be used.

Each case must be decided on its merits, and so much depends on attention to detail, that we should sometimes be deterred from commencing catheterization with a careless and slovenly patient, when we should have resorted to it could we have counted on his intelligent co-operation.

Guyon has laid down a rule of practice for these advanced prostatic cases, which is a good one.

He puts the patient upon general tonic treatment, and if he finds that he is wanting in strength sufficient to benefit by it, he does not regard him as in a state likely to be helped by interference with his bladder. If, however, he improves decidedly in his general condition, then Guyon regards it as wise to resort to the catheter.

The precautions to be observed in accustoming the patient to the catheter are the same that are required in the second stage of the disease, but they are now even much more important.

Especially should the sudden emptying of a distended bladder be guarded against. It may often require two or three weeks of catheterization before the bladder acquires such tolerance that it may safely be left empty.

During the preliminary period the catheter should always be passed with the patient horizontal, to guard against the too rapid flow of water; afterward, when the complete emptying of the bladder is desired, the vertical position is the best for this operation.

Treatment of Complications. Cystitis, which is the most common complication of prostatic hypertrophy, is to be treated according to the rules laid down under Diseases of the Bladder, on pages 514 and 515, in vol. i. of this HANDBOOK.

When it occurs in the first stage of the disease, general treatment is to be first thoroughly tried, and local treatment through a catheter is to be resorted to only when simpler measures fail. In the second and third stages, when partial retention exists, the systematic evacuation and irrigation of the bladder is the most efficient means of treatment at our command.

FIG. 3126.—Mercier's Prostatome, with Cutting-blade, L, and Set-screw, V, V.

Nephritis, or pyelo-nephritis, must be treated on general principles. Mustard poultices over the lower dorsal and lumbar regions during the acute stage, with, afterward, careful rubbing and friction to keep up the action of the skin; a bland, non-stimulating, but nutritious diet in abundant quantity, and regulation of the bowels. If uræmia threatens, pilocarpin and hot-air baths may be used to promote elimination, and to relieve the congestion of the kidneys.

A stone in the bladder can usually be removed readily by litholapaxy through an enlarged prostate, unless it is of great size and hardness, or unless the careless use of instruments has produced false passages. The pocket behind the prostate often holds a small stone concealed, and makes it hard to seize, in which case the hips may be raised so that the stone rolls back toward the fundus, where it is easily found and crushed.

When micturition is very difficult, it may sometimes be thought wise to remove small stones by perineal incision, in the hope of, at the same time, relieving the obstruction.

When litholapaxy is impossible on account of the size and hardness of the stone, it is usually necessary to resort to the supra-pubic incision. By this operation, too, a prominent middle lobe, or other cause of obstruction, may sometimes be removed.

RADICAL OPERATIVE TREATMENT.—Finally, we have to speak of the various operations which have been devised for the relief of obstruction in the prostate. These may be divided into the internal and external operations.

The internal operations are mainly useful in the treatment of those cases in which the obstruction assumes the form of a bar, and are not so applicable to cases of greatly hypertrophied and projecting third lobe. They may consist in simple incision, or in excision, of a portion of the obstructing part.

Mercier, who was a strong advocate of these operations, devised two instruments for their performance.

One, for making a simple incision, is shaped like a short-beaked sound, and carries a concealed knife which can be made to cut upon either the concave or convex side of the beak. The bar can, therefore, be divided by hooking the beak of the instrument over it, and then, by withdrawing the blade, making an incision, the length of which can be exactly regulated by a set-screw in the handle.

An incision can also be made from before backward by placing the heel of the beak in front of the obstruction with the point upward, then making the blade pro-

trude on the convex side and advancing the instrument into the bladder.

When the bar is of considerable width or forms much of a projection, Mercier uses another instrument somewhat like a lithotrite. The obstruction is engaged between the blades of this, and as the instrument is closed it punches out the part included. If enough is not removed the first time the operation is repeated.

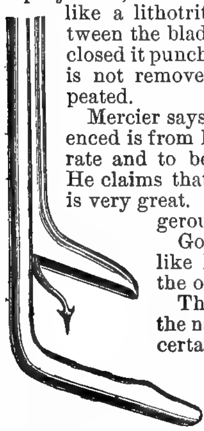

Fig. 3127.—Blades of Mercier's Instrument for Punching out a Piece of the Obstruction.

Mercier says that the only difficulty ever experienced is from hæmorrhage, which is usually moderate and to be overcome by appropriate means. He claims that the relief following the operation is very great. Other operators have reported dangerous hæmorrhages.

Gouley has also an instrument not unlike Mercier's, and he claims priority in the operation.

The necessity for an exact diagnosis of the nature of the obstruction, and the uncertainty in the thorough performance of the operation, limit very much its usefulness.

The perineal operation consists in a median incision down into the membranous urethra. Through this opening the finger is passed along the prostatic urethra, and under its guidance a probe-pointed knife is introduced and a section made through the obstruction. A good-sized tube is then fastened into the bladder through this opening. This tube by its pressure checks hæmorrhage, provides dependent drainage, and, by holding the wounded surfaces apart, moulds the urethra during healing.

The prostatic urethra admits of such dilatation that, if a polypoid projection is found it can be removed with a small tonsillitome or wire noose.

This operation, which owes its present prominence to Mr. Harrison, is a very useful one, and has the great advantage of giving thorough drainage and a long rest to the bladder. The relief to the obstruction is often, if not usually, very satisfactory.

The tube should be kept in place for a number of weeks or even months, and before it is finally left out, the patency of the canal should be tested. Usually the first indication that it may safely be removed is the appearance of urine along the urethra.

As has been stated above, the prostate may be reached and operated on by the supra-pubic incision. This method, however, introduces special dangers and has no advantage over the perineal operation, except in cases complicated by obscure bladder lesions.

Atrophy of the prostate may occur as the result of mechanical pressure, or of destruction of portions of the organ by inflammation. It may also appear in the course of an exhausting disease, or as a consequence of old age. It gives rise to no symptoms and calls for no treatment.

Tumors of the Prostate.—These may be classified as follows:

Cysts	Retention Cysts. Hydatids.
Myoma Adenoma	Adeno-myoma.
Sarcoma	Round cell. Spindle cell. Lympho-.
Carcinoma	Scirrhus. Colloid.

Retention cysts formed from dilated gland acini occur in many old prostates. They are always small, and give rise to no inconvenience. Their contents are sometimes inspissated, forming little concretions.

Hydatid cysts of the prostate are so rare that Thompson could, in 1883, learn of but one; and even in that case it is doubtful whether the cyst started in the prostate or near it. When discovered they should be at once emptied.

Pure myoma is very rare; adenoma is somewhat less so, but adeno-myoma is the most common of prostatic growths. Paul thinks ordinary hypertrophy should be ranked under this head.

The universal, symmetrical enlargement can hardly, as it seems, be classified as a tumor, and yet the pathological process is the same in it and in the circumscribed masses which we recognize as new-growths. These may project into the urethra, the bladder, and in other directions, or they may be buried in the midst of the gland-tissue, from which they can be easily shelled out.

These tumors have sometimes been removed during section of the gland in lithotomy or other operations, and the removal of projections into the urethra has been considered above.

Sarcoma is occasionally observed in the prostate, where it may start primarily, or to which it may transplant itself from the testicle or elsewhere. It usually appears early, but may develop late in life.

Carcinoma is still less common than sarcoma, and appears ordinarily after middle life. It may assume a scirrhus or a colloid type.

In either of these last two malignant forms of growth there may be a good deal of pain and considerable hæmorrhages, especially after instrumentation.

In carcinoma the neighboring lymphatic glands are likely to be early involved.

Any cyst or tumor of the prostate may give rise to symptoms of obstruction. The difficulty of micturition may reach a point to require some operation for its relief. In opening the bladder for drainage under these circumstances, either the perineal or the supra-pubic incision may be used, and the selection would depend somewhat upon the size of the tumor.

If this is large and of a malignant character which makes its removal evidently impossible, supra-pubic drainage would be preferable.

On the other hand, in the case of a smaller or non-malignant tumor the perineal incision should be used, as by it the exact condition of things can be ascertained and possibly benefited. Harrison reports a case in which he removed a cancerous growth as large as the last phalanx of the thumb from the prostatic urethra. The operation was followed by great relief from distress in micturition, and the patient lived for fourteen months.

Tuberculosis of the Prostate occurs often secondarily to tubercular conditions in other parts of the genito-urinary tract. It probably also appears sometimes primarily in the prostate.

As patients with genito-urinary tuberculosis usually die when the disease is far advanced, it is rarely possible to decide at autopsy where the disease originated, and as the organs are many of them deep-seated and beyond the reach of physical examination, it is likewise impossible during life to be sure that the prostate was primarily affected.

On the other hand, this gland is situated at the junction of the genital and urinary passages, is as it were at the cross-roads through which any tuberculous material from the kidneys or testicles must go in its passage from the body. This situation makes it peculiarly liable to secondary infection, and, as a fact, it is almost always sooner or later involved.

The tubercles may appear as little isolated gray granules, scattered throughout the tissue of the organ, or they may be agglomerated into masses which, if they reach a moderate size, ordinarily become cheesy in the centre and finally break down into abscesses.

Sometimes almost the whole prostate is thus destroyed, and its place is occupied by an abscess which usually communicates with the urethra and bladder. It may break through into the rectum, forming a recto-vesical or urethral fistula directly through the prostate.

The *Symptoms* are those of a chronic prostatitis (see above) with a special tendency to hæmorrhage. They may be associated with evidences of tuberculosis elsewhere.

Physical Examination by the rectum may reveal little or no alteration in the gland. Ordinarily, however, inequalities are felt which may give it a distinctly

nodular character. This may be associated with enlargement, or the prostate may preserve almost its normal size.

The ejaculatory ducts and the vesiculæ seminales should be felt for, and if the disease has affected them, they may be found as thickened, resistant, cord-like bodies. This is especially to be observed when the disease started in the testicle and worked its way up to the prostate.

Not infrequently a little shot-like mass is felt between the rectum and the prostate, or it may be a little behind and to one side of the gland. It is not attached to the prostate, rectal wall, or seminal vesicles, but is loose in the tissues between them.

Dr. Bryson, of St. Louis, thought that in one case, in which he had an autopsy, he made it out to be a cheesy mass within a vein. Possibly it is sometimes an infected lymphatic gland.

The testicles, epididymes, and vasa deferentia should also be examined, and the urine should be investigated for evidences of kidney complication and for tubercle-bacilli.

These last are very difficult of detection in the urine, and their apparent absence does not argue against tuberculosis. When unmistakably present they are conclusive confirmatory evidence.

The physical investigation should also include the examination of the lungs, which may share in the tuberculous process.

Diagnosis.—The disease may be confounded with chronic prostatitis or cystitis, with stone or tumor in the bladder, or with pyelitis when accompanied by frequent micturition.

While a careful consideration of the symptoms and inherited tendencies of the patient may enable us to form a probably correct idea of the condition, it is only by a careful physical examination that we can reach a positive diagnosis.

Besides the examination described above, an exploration of the bladder, under ether if necessary, will be needed for the detection or elimination of stone and of tumor of the bladder.

There will be a certain number of cases in which a diagnosis is at first impossible, and in which the true interpretation of the condition can be reached only when time has developed characteristic symptoms.

Treatment.—Most important is the constitutional treatment with cod-liver oil, hypophosphites, and iodides. A healthy out-of-door life, with moderate exercise and good food, are to be enjoined.

Thompson advises against local treatment, and it is certainly important to avoid rough manipulation.

In the early stages of the disease, however, gentle local measures may serve rather to allay than to excite irritation, and should be tried.

Irrigation of the prostate and bladder, and the introduction of iodoform pencils, may be of service. Occasionally the passage of a sound is useful by removing the contraction of the constrictor muscle. The pain and frequency of micturition may sometimes be much relieved by these means.

While the prognosis is necessarily grave, and the permanence of improvement is always doubtful, still these cases are not always hopeless if seen early.

PROSTATIC CALCULI.—In the ducts and dilated tubules of the prostatic glands are found not infrequently little yellowish or brownish bodies, composed of an organic substance allied to protein.

These, if they increase beyond a moderate size, begin to have earthy salts deposited in and around them, and finally become prostatic calculi, which may reach the size of a walnut, or even larger.

These calculi are usually multiple, and are facetted from mutual attrition. They are hard, take a high polish like porcelain, and are white or light-brown in color.

Chemically, they are composed almost wholly of phosphate, with a slight admixture of carbonate, of lime, and are to be distinguished from urinary calculi by the fact that they do not contain any of the triple phosphate of magnesia and lime, which is so large a constituent of vesical calculi.

When prostatic calculi are made out they may be removed by a median or lateral perineal incision. The operation is usually one of no serious danger, as the bladder is not opened.

Arthur T. Cabot.

PROTOPLASM. Wherever in nature that group of phenomena which we call vital is manifested, we find it invariably associated, whether in higher or lower beings, in animals or plants, with a particular form of matter which is called *protoplasm*. Protoplasm is living matter.

The exact chemical constitution of protoplasm is unknown; but its proximate analysis, after being deprived of its vitality, shows that in this dead condition it contains proteids, carbohydrates, fats, certain inorganic salts, and water.

Physically, as seen with high powers of the microscope, protoplasm appears to be nearly homogeneous, or to consist of a structureless, semifluid material in which are suspended granules and minute fibrils.

In the higher, and in most of the lower animals and plants, protoplasm exists in the form of tiny lumps of various shapes and sizes, which are called *cells*. For a detailed description of these cells, and the life-characters which they display, consult the article on Cells.

While the phenomena of life are never manifested except in connection with this particular form of matter called protoplasm, whether in animals or plants, we should not be led by the apparent simplicity and comprehensiveness of the statement into a belief that we know very much about its real nature. "Life is a property of a certain kind of compound matter." To this matter we give the general name protoplasm. But it should not be inferred from this that protoplasm is everywhere identical in its constitution. On the contrary, it would seem that it must be actually as varied as are the manifestations of life which we observe in the different forms of cells, although this variation is not evident by any chemical or physical means of analysis at present known.

The term protoplasm is sometimes used in a purely anatomical sense, to signify that part of the cell which immediately surrounds the nucleus, and which is more properly called the cell-body.

Parts of certain cells, as the membranes of some forms, or the entire body, as in epidermic scales and some of the cells of the hair-shaft, may become converted into a dense material, which, though contributing to cell-structure, does not exhibit the phenomena of life and is often called, though the expression is not a proper one, dead protoplasm.

T. Mitchell Prudden.

PRUNE (*Prunus*, U. S. Ph.; *Prunum*, Br. Ph.; *Prunier commun*, Codex Med.). The fruit of the garden Plum, *Prunus domestica* Linn., order *Rosaceæ*, dried in the sun or by artificial heat. This well-known fruit-tree is said in Bentley and Trimens' "Medicinal Plants," to be probably descended from *P. insititia* Linn., a thorny shrub with pubescent twigs and spherical fruits (purple-black, yellow, or green), growing wild in the mountains of Western Asia, Greece, etc., and also cultivated. The common Plum-tree has no thorns, but smooth branches and an oval fruit, of blue-black or yellow color, covered with a thin layer of waxy "bloom." The varieties are numerous; of these the source of French Prunes is var. *Juliana* D. C., that of German Prunes var. *Œconomica* Bork; but other varieties are also dried, and it is to be doubted whether the source of any particular sample can be always determined. Plums have been cultivated for more than twenty centuries. Prunes need no description, they are kept in large quantities by the grocers, in every quality, from the poorest, in bulk—small, excessively shrivelled, hard, and nearly tasteless—to the best, imported in glass jars or fancy boxes.

They contain *sugars* and *fruit acids* (malic, etc.), "*pectic* and *albuminoid substances*," etc., and are chiefly consumed as dessert, or in sweet sauces, puddings, or pies. In large quantities they are a slightly laxative food; they

can scarcely be called medicine, and would be dropped from the officinal list, only that they are employed in the Confection of Senna (*Confectio Sennæ*, U. S. Ph.), of which they compose seven per cent. The syrup of "stewed prunes," made thick and sweet, is an excellent laxative for infants; they take it readily, and it produces very little unpleasant disturbance. Dose, a teaspoonful.

Allied Plants.—See Almonds.

Allied Drugs.—Figs, Raisins, Tamarinds, Cassia Fistula, etc.

W. P. Bolles.

PRURIGO. Syn.: Prurigo (Hebra); Juchblattern, Ger. Before Hebra described a distinct disease under the name of prurigo, the term included a number of affections which were dissimilar in various respects. Almost anything which had *itching* as one of the symptoms was liable to be put down as a form of prurigo. Pruritus was prurigo, and prurigo was pruritus—a confusion of terms which still to a large extent exists among the older general practitioners. They should not be confounded, for the dermatologist recognizes prurigo as a disease *sui generis*, while pruritus is only a symptom.

Prurigo is a rare disease in North America. The reports of the American Dermatological Association for the last three years give 19 out of a total of 38,320 cases of skin diseases reported by the different members. Foreign dermatologists are incorrect in suggesting that the disease is overlooked in this country. The fact is, it hardly exists here; and if cases are seen, they are most often in those who have come into the country from abroad, bringing it along with them.

As described by Hebra, the disease is divided into prurigo simplex seu vulgaris and prurigo agria seu ferox, according to its severity and duration. It always begins in early life, and is generally foreshadowed by the appearance, upon the extremities of an infant, of constantly recurring urticarial wheals. After the second year of life an eruption of small papules, the size of a mustard- or hemp-seed, makes its appearance, and we then have true prurigo.

Primarily, the papules are more perceptible to the touch than to the sight. The hand when run over the skin feels the minute nodules before the eye can detect them, projecting above the level of the surrounding epidermis. As time goes on, this roughness of the skin to the touch is even more pronounced, so that the hand feels as if it were being rubbed upon coarse sand-paper.

After the papules appear, itching commences, and the child is seen to scratch. A drop of clear-colored serum forms a vesicle at the top of the papule, the epidermis becomes thin, is then scatched off, and the serum escapes, while further scratching may rupture the capillaries already dilated, forming a crust of blood and serum. After years of recurring eruption and scratching, the skin becomes thickened, hardened, brittle, parchment-like, and pigmented. The patients are unable to resist the impulse, and spend the greater part of their lives in scratching. Even in sleep there is no cessation. Unconsciously, all night long they are at work, so that the regular grating sound, coming from the beds of long-suffering prurigo patients at night, is one of the most weird and unpleasant noises imaginable. It is as regular as their breathing.

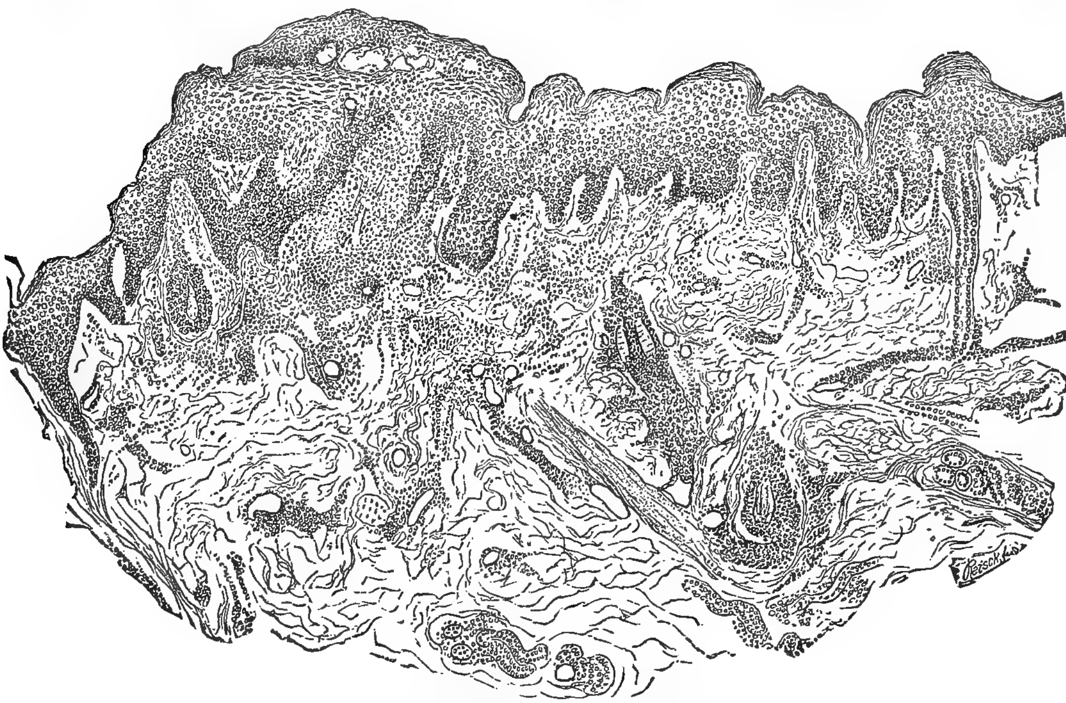

Fig. 3128.—Prurigo Papule.

The disease most generally begins upon the extremities, where it is also most intense. The papules appear first in this situation, and then, in order, upon both sides of the thorax, the abdomen, the back, and the buttocks. They do not appear on the scalp, and seldom in the axilla, the palms, the flexor surface of the knee-joint, or on the genitals. In cases of long standing the lymphatic glands are enlarged.

Histological investigation of the papule, made by the present writer,[1] shows that it is formed by an infiltration beginning around the upper layer of vessels of the corium; this infiltration, extending upward, surrounds the papillary vessels and enlarges the papillæ, thus pushing up the epidermis, which becomes thickened at an early stage above them (see Fig. 3128). Finally, this infiltration, penetrating the epidermis, forms with its layers a small vesicle containing serum, blood, and lymph-cells. The signs of infiltration surrounding the hair-sheaths and sweat-ducts are secondary, and they play no especial part in the process. Their presence in the papule is ac-

cidental, and it is certain that the primary changes in the skin are not in connection with them.

The color of the papule at first does not differ from that of the surrounding skin, on account of the depth of the slight infiltration with which it begins. At this stage there is no itching, but later on, when the infiltration has become greater this symptom begins.

Hebra says prurigo is incurable; the symptoms may be alleviated by proper remedies, but there is no permanent cure. The therapeutical indications are to remove the dry, brittle epidermis, to soften the skin, and to allay the itching. Warm baths, continued for hours at a time; stimulating soaps, such as spiritus saponis alkalinus; ointments of vaseline, lanolin, or simple cerate, containing zinc, salicylic acid, or sulphur; medicated gelatines, and attention to the general health, are some of the means employed to relieve the sufferer. It is a disease of the poorest, most ill-fed classes—such classes as know no hygienic laws, and have for successive generations been in the same unhealthy condition. Fortunately, we have as yet no such classes in this country; hence the rarity of the disease with us.

Robert B. Morison.

¹ A Contribution to the General Knowledge Concerning the Prurigo-Papule, American Journal of Medical Sciences, October, 1883.

PRURITUS. A neurosis of the skin, characterized by local or general itching, without any perceptible primary lesion.

PRURITUS UNIVERSALIS usually affects larger portions of, or even the entire surface, and may occur at any age or in either sex. It is not infrequently accompanied by some disturbance of the abdominal organs, as granular liver, hepatitis, Bright's disease, etc. In young women, disturbance of the menstrual functions and, in older women, pregnancy sometimes occupy a causal relation to general pruritus. In still older persons, and especially in the aged, general pruritus not infrequently occurs in its severest and most stubborn form, probably in connection with the senile changes in the skin, forming a most distressing malady.

PRURITUS LOCALIS occurs commonly in certain regions by preference. Thus we have *pruritus ani,* which usually occurs in connection with hæmorrhoids or, in children, with seat-worms. The affection usually first shows itself at the muco-cutaneous junction, and spreads forward toward the perineum and backward toward the coccyx. Pruritus ani is usually worse in the evening on undressing, and when the patient becomes warm in bed. In the semi-unconsciousness of sleep the parts are rubbed and scraped until an artificial eczema results, and, in fact, more or less eczema is present in most severe cases of pruritus ani.

Pruritus genitalium takes on a somewhat variable aspect, according to the sex. In men the scrotum is the usual seat of the disease. Pruritus scroti is a not infrequent accompaniment of pruritus ani. In the earlier stages of the disease no lesions are perceptible, but after the affection has lasted for some time excoriations and blood-crusts appear as secondary lesions, the result of scratching. Here, too, artificial eczema sooner or later results, although the writer has observed numerous cases where, even after prolonged and severe pruritus, no perceptible lesions could be observed upon the scrotum. Pruritus scroti is always a stubborn affection, and sometimes becomes chronic, resisting every attempt at relief, and at times driving the patient nearly frantic.

Pruritus pudendi muliebris commonly occurs in the mucous membrane about the labia minora and majora, and in the neighboring muco-cutaneous surface. Occasionally it seems to be confined to the clitoris and its immediate surroundings. In children, ascarides are often the cause of the itching; in adult females, uterine disease, leucorrhœa, vaginismus, etc., give rise to the trouble. Not infrequently, however, no known cause can be ascertained, and the affection appears to be purely idiopathic. European writers often allude to this affection as the cause of onanism and nymphomania. The writer has never observed this result excepting among the insane, and is not disposed to regard pruritus pudendi as a frequent cause of these neurotic manifestations in persons enjoying the full use of their mental faculties. This form of pruritus is connected at times with diabetes mellitus.

Pruritus palmaris and plantaris are forms of local pruritus which may be mentioned. They are rarely severe or long continued, and are usually more amenable to treatment than the other forms.

A form of local pruritus due apparently to changes of temperature is that first described by Duhring as *pruritus hiemalis,* or winter pruritus. This form is commonly observed upon the lower extremities, particularly the insides of the thighs and the calves, although sometimes it may occur upon the upper extremities, and may assume an almost universal form. The peculiarity of pruritus hiemalis is that it leaves its victim free during the summer months, only to return promptly with the frosts of autumn, year after year. During the winter months a spell of clear, bright, frosty weather will bring on a tormenting attack, which will pass away when the weather becomes warm and moist. The itching comes on when the patient takes off his clothing at night, and seems to be excited by the impact of cold air. In the majority of cases it passes off as the patient grows warm in bed. Severe cases may, however, continue through the entire day, and even torment the patient at night.

The *diagnosis* of pruritus should give rise to no difficulty, because, although there are other diseases in which itching is a prominent symptom, these are always characterized by primary lesions of some sort. The history of itching as the first symptom, with visible lesions occurring only secondarily, if at all, is conclusive.

Old cases of pruritus are almost always accompanied by a certain amount of eczema, with scratch-marks, papules, fissures, crusts, pigment-deposit, etc., and it may at times require careful investigation to ascertain the character of the original disease. Of course, the possible presence of parasites must always be considered and excluded (see Pediculosis).

The *treatment* of pruritus is always difficult, and will at times require every therapeutic recourse and the most careful examination and study of the patient's whole economy.

There are few skin diseases in which it is more necessary to examine every possible weak point, and yet cases not infrequently occur in which the practitioner must proceed on a basis of pure empiricism, and simply employ one remedy after another until something or some combination is secured which will attain the desired end.

As regards drugs, the usual tonic and alterative medicines are to be employed. Irregular menstruation must be treated by the judicious use of iron or other remedies, cod-liver oil, etc. Quinine and strychnine are sometimes of use. Recourse may be had to bromide of potassium and chloral, alone or together, in order to subdue general nervous symptoms. Morphia should in no case be used, as it tends to aggravate the itching.

External treatment affords great relief, and is to be used in all cases. Hot and cold douches, used alternately, or hot water applied as hot as it can be borne, or plain vapor-baths, are often useful. Medicated baths, containing from three to six ounces of bicarbonate of sodium, or from two to four ounces of carbonate of potassium or borax, to thirty gallons of water, will at times afford relief. Sulphuret of potassium and sulphur vapor-baths are sometimes used with success. Inunctions with a bland oil, as almond-oil, may be practised after these baths.

Lotions of various kinds are the most generally useful applications in pruritus, and those containing carbolic acid are by far the most generally efficient. Chloroform; chloroform and alcohol, a drachm to the pint; lead-water; dilute water of ammonia; dilute nitric acid, ten minims to the ounce of water; vinegar—are all serviceable remedies which may be tried singly or in succession

in troublesome cases. The following tar-preparation, known as liquor picis alkalinus, and introduced by Bulkley, is generally useful: ℞. Picis liquidæ, 64 Gm. (℥ ij.); potassæ causticæ, 32 Gm. (℥ j.); aquæ, 160 Gm. (℥ v.). M. This is very strong and must be diluted with from three to ten parts of water. In some localized forms of the disease, ointments are to be used in preference to lotions. One of carbolic acid, ten to fifteen grains to the ounce of oxide of zinc, is often useful.

In pruritus of the female genital organs, water as hot as can be borne, sponged upon the parts, forms an admirable anæsthetic and should be used in all cases, whatever other treatment may be added. Following this, carbolic lotions, sulphurous acid—sulphite of sodium, in solution of a drachm to the ounce of water—and lotions containing hydrocyanic acid may be employed. Sometimes an emollient poultice of freshly made almond-meal, which evolves a small quantity of hydrocyanic acid, will be found very soothing. Where the itching is localized, particularly about the clitoris, a ten-per-cent. solution of hydrochlorate of cocaine, painted on, will give an exquisite sense of relief for a time, and may even prove curative.

Pruritus of the anus is best treated by oils or ointments. Carbolized oil, in the strength of twenty per cent., and ointments of belladonna or tar are usually beneficial. Applications of hot water should precede the use of the medicinal agents. Sometimes a pledget of lint wet with a five-per-cent. solution of hydrochlorate of cocaine will relieve the pruritus like magic.

Pruritus of the scrotum is often very intractable, the more so because the skin is thin and not infiltrated and its surface is intact. It is difficult to get any local remedies in direct contact with the diseased parts. The following formula is much used: ℞. Bismuthi subnitrat., 8 Gm. (ʒ ij.); acid. hydrocyanic. dil., 8 Gm. (f ʒ ij.); mist. amygdalæ, 32 Gm. (f ℥ iv.).

In the pruritus of jaundices, mercurial ointment is said to be of value; also, lotions and baths of vinegar, in the proportion of two quarts to an ordinary thirty-gallon bath, or of nitric acid, in the proportion of two to three ounces to the bath.

The *prognosis* of pruritus should be guarded. The disease, as a rule, is obstinate; often extremely so. The prognosis often depends largely upon the cause and our ability to remove it. In grave cases melancholic symptoms may be present. Occurring in the aged, the prospect of ultimate cure is poor.

Pruritus hiemalis, though usually less severe, is perhaps even more intractable than the other forms of the disease. *Arthur Van Harlingen.*

PSORIASIS. A chronic affection of the skin, characterized by the appearance of reddish, slightly elevated, dry, inflammatory patches, variable as to shape, size, and number, covered with abundant, whitish or grayish mother-of-pearl-colored, imbricated scales. The disease varies greatly in its extent and intensity in different cases, sometimes showing a typical development, in other cases represented by one or two obscure lesions. It possesses, almost invariably, however, certain characters which serve to identify it. The lesions begin as small, reddish spots, scarcely raised above the level of the skin, which almost immediately become covered with whitish scales. They often develop rapidly, reaching the size of coins in a few weeks. At other times the course of the disease is more sluggish. The extent of the eruption varies greatly. A few patches may be all that are present, or the entire surface from head to foot may be involved, with scarcely a clear spot to be found. Commonly the disease shows itself in the form of scaly patches, of varying size, scattered over different parts of the body. The patches are characteristic. They are usually rounded, sharply defined from the surrounding skin, and consist of a mass of imbricated, yellowish-white scales on a red base. When the scales are picked off, a smooth, shiny, reddish surface is shown underneath, on which can be perceived a few drops of blood the size of pin-points. The abundance of the scales is a marked feature in some cases. Where they are formed rapidly—that is, in well-developed cases—the patient's bed may be filled in the morning with a handful of scales which have accumulated during the night. When the disease exists about the joints, fissures may show themselves, so deep at times as to make movements of the affected limb painful. There is no watery discharge at any period of the disease. Sometimes the eruption takes on a highly inflammatory character, with redness, swelling, and severe burning and itching, while at other times all these symptoms are much less marked, and, in fact, the patient would hardly be aware of the existence of the disease, did he not see the eruption. Though the individual patches of psoriasis may be, and generally are, small, yet they sometimes coalesce into patches the size of the hand or larger, or may even cover the greater part of a limb.

Psoriasis may occur on any part of the body, but is most apt to be seen on the extensor surfaces of the limbs. It is sometimes found on the elbows and knees when it shows itself nowhere else. On the other hand, it may be absent from these localities, although present at many other points. The back is more commonly attacked than the chest, and in women a favorite seat of the eruption is around the waist where the skirts are tied. The scalp is a frequent seat of the disease. In this locality it sometimes occurs in patches, but more frequently as a diffuse and abundant scaliness. It is apt to extend a little beyond the border of the scalp, especially behind the ears and on the forehead, and this is quite characteristic. Psoriasis does not occur upon the mucous membranes. The so-called "psoriasis" of the tongue is probably only a precursory hardening leading to epithelioma. Psoriasis is not contagious.

The cause of psoriasis is not known. It is apt to occur in well-nourished, rosy-complexioned, light-haired people, the "picture of health" excepting that they are apt to be a little rheumatic. Now and then, however, it is met with in thin, worn persons who are in poor health. Greenough's statistical inquiry into this point confirms the writer's view. Psoriasis is not often encountered in children, though Stelwagon has reported a case where it occurred in a child between three and four years of age, and Greenough's statistics show of 150 cases 20 which were known to have first occurred under the age of ten. On the other hand, 6 cases out of those observed by Greenough first showed signs of the disease after passing the fiftieth year. It is the opinion of the writer that psoriasis occurs much more generally than is supposed at an early age, but the disease is not apt to be noticed until it grows with the growth of the individual and becomes more pronounced. Greenough succeeded in obtaining a history of hereditary or family tendency in 31 cases out of 97, but the tendency to hereditary transmission has not been observed by most writers or has been considered rather exceptional. Some cases of psoriasis are worse in winter and disappear almost or entirely in summer; others are worse in summer. Diet, I believe, has little influence in causing the disease, though in some cases it may influence its course quite markedly. Psoriasis and syphilis are not connected in any way. There is a syphilitic eruption sometimes called "syphilitic psoriasis," because the lesions resemble those of psoriasis. This most unhappy term has caused much confusion of mind, but it must be remembered that the cause, course, and treatment of syphilis differ *in toto* from those of psoriasis (see under Syphiloderma).

The diagnosis of psoriasis is easy when the affection is well developed and presents its typical appearance. The form and aspect of the lesions, and the history of the case, will usually serve to determine its nature. Scanty and ill-developed eruptions of psoriasis are, however, at times distinguished only with difficulty. Nevertheless, it is an important matter to accurately determine the nature of the disease, for its treatment is widely different from that of the affections with which it is liable to be confounded; its prognosis is also different, and, in addition, two of the other affections are contagious.

Two or three small patches of psoriasis occurring alone

upon the arms or legs may be mistaken for *eczema*. Itching, however, is almost invariably present in eczema, and therefore itching is one sign that an eruption in question is not of this nature, though not a sure sign, since psoriasis also sometimes itches.

In the majority of cases of eczema there will be a history of moisture at some time. Psoriasis is always dry and scaly, never moist. The scales of psoriasis are more abundant, larger, and whiter than those of eczema. The patches of psoriasis are usually bold and well defined in outline, while those of eczema fade into the surrounding skin.

Syphilis in the form of the papulo-squamous syphiloderm is very apt to be mistaken for psoriasis, and *vice versâ*. Psoriasis, however, is more apt to be symmetrical in its distribution. It often involves a large portion of the surface at once, or is found in regions remotely separated, which is rarely the case with the papulo-squamous syphilitic eruption. In psoriasis the lesions seem to be on the surface, so to speak. They are very scaly, but without much infiltration. The syphiloderm, on the other hand, is deeply indurated, and is only scantily covered with scales. In psoriasis the knees and elbows are apt to be involved. In syphilis these are not often attacked. Occurring on the palms and soles the disease is almost certain not to be psoriasis, which is very rare in this locality. The color, though often deceptive, sometimes aids in diagnosis. It is usually much lighter in psoriasis, while in syphilis it is apt to be a dusky ham-color. The age of the patient and the duration of the disease may give a clew to the diagnosis. Psoriasis generally first shows itself before the age of twenty; this form of syphilis, later. The history of psoriasis is that of a chronic disease lasting for years, continuously or in an intermittent manner. Syphilis rarely retains one form for any length of time. Other points in the history—infection, the occurrence of other lesions, etc.—may come into use. Itching is rare in syphilis, common in psoriasis, but too much reliance must not be placed on this symptom. It has been the writer's misfortune to see several lamentable mistakes made by the exclusion of syphilis based on the presence of itching. Finally, the touchstone of treatment may be resorted to in very obscure cases.

Tinea circinata and psoriasis are sometimes mistaken for one another, but the patches of tinea are less inflammatory, red, and infiltrated, and are much more superficial. The scales in tinea are larger and lighter, and the patches show no attempt at symmetry. The microscope shows the existence of a fungus in the scales of tinea circinata, which is absent in psoriasis, and a history of contagion may often be obtained in the former disease, which is absent in the latter.

Psoriasis may occasionally be mistaken for seborrhœa, as this disease occurs on the chest and back. A comparison of the description just given of psoriasis with that of the former disease will show in what points the difference lies, while it may also be kept in mind that seborrhœa affects a small patch, the size of the hand, over the sternum in front and the region of the scapulæ, with the parts between them, behind. From seborrhœa capitis and from pityriasis capitis, psoriasis of the scalp is distinguished by the yellow, friable character of its scales and their abundance, the scales of seborrhœa being markedly oily and adherent, while those of pityriasis are gray, thin, and powdery.

Psoriasis may occasionally be mistaken for lupus, especially lupus erythematosus; but in addition to the fact that lupus erythematosus is most likely to be encountered on the face alone, whereas psoriasis is almost always found coincidently in other localities, the more scanty scaliness of lupus and the greater amount of infiltration also serve to distinguish between the two affections. The description of both forms of lupus may be referred to in this connection.

It is said that psoriasis may be confounded with lichen ruber. This certainly cannot occur very frequently in this country, the forms of lichen ruber commonly encountered here being easily distinguishable. Lichen ruber usually occurs upon the extensor surface of the forearms, at least in the milder cases; the lesions are uniformly of small size, not much larger than a pin-head or small split-pea, while the lesions of psoriasis vary from the size of a pin-head to that of a coin, with occasional larger patches. The lesions of lichen ruber have few scales, while the lesions of psoriasis are very scaly.

The anatomy of psoriasis has been made the subject of careful study by Robinson, whose description shows the affection to consist in a hyperplasia of the rete and corresponding structure of the hair-follicles. In a section of a lesion of a few days' duration the corneous layer is found to be but slightly changed. Prolongations downward of the interpapillary portion of the Malpighian layer, which are more extensive in the central, *i.e.*, older portions of the lesion, are seen in microscopic sections of older lesions. In the papillæ and superficial part of the corium within the psoriasis regions there are seen enlarged blood-vessels and round bodies in varying numbers in the surrounding tissues, while in the non-papular region no enlargement of blood-vessels is as a rule observed, and also no white blood-corpuscles. The deeper parts of the cutis appear normal, as well as the sebaceous and sweat-glands.

The increase in the thickness of the Malpighian layer arises from an increase in the number of rete-cells. This increase is sometimes very great. The blood-vessels, also, in the papillæ are more or less dilated, this dilatation, together with the emigration of white blood-corpuscles, increasing with the duration of the eruption. All the inflammatory changes, however, in the cutis are secondary to the hyperplasia of the rete.

The hair in psoriasis becomes changed at the commencement. The external root-sheath, the structure cor responding to the rete, becomes increased in size in the same manner as the latter structure. There is a real hyperplasia, with an extension of the hyperplastic structure into the surrounding cutis. This growth occurs principally at the root of the hair, though it is met with also along the rest of the follicle.

During the period of disappearance of the disease there is a gradual return to the normal condition, until the hyperplasia, dilatation of the blood-vessels, and cell-infiltration have completely disappeared. The Malpighian prolongations become smaller and smaller until the layer attains its normal size; the blood-vessels gradually return to their normal diameter, and the round cells and serous exudation to their normal channels. Of these pathological processes, the cell-infiltration and œdema generally disappear first, and the hyperplasia last. Psoriasis may sometimes undergo degenerative changes and become changed into epithelioma, as has been shown by White.

The *treatment* of psoriasis must be in most cases both internal and external. The constitutional treatment of the affection should be based on a careful study of the history and habits of the patient. Attention should be given to the patient's general health and his condition, whether stout and well nourished or thin and delicate. Regard must be had also to any functional derangement. The history of the eruption itself must be inquired into, as to its acuteness or chronicity, as to local and constitutional treatment which may have been previously employed, together with the effects of the same. In addition, inquiry should be made regarding the influence of the seasons, and whether the eruption is apt to disappear for a time and then to break out again.

Fortified with this knowledge, the medical treatment can be entered into intelligently. In the large majority of cases, arsenic is pre-eminently the remedy. But while arsenic is as near a specific as, in the nature of things, it is possible for any medicine to be, yet it must be employed judiciously if its good effects are to be obtained, or even if we do not wish to do harm. Arsenic should not, as a rule, be administered where there is much gastric irritation, and it is hardly necessary to say that it should not be continued, should it disagree even slightly. The patient should be warned of its possible effects, and should be under the constant watch of the physician; on the first symptom of indigestion, pain in the stomach or

bowels, or diarrhœa, the dose should be lessened or the use of the medicine suspended. Large or almost toxic doses do not hasten the cure of psoriasis; they sometimes even retard it by upsetting the stomach. Sometimes only a minute dose, as half a minim of Fowler's solution, is borne at first, when, later, tolerance is gained and a full dose may be given. Some persons need and will bear large doses of arsenic, but this idiosyncrasy must be learned by careful tentative increase of the dose, beginning always with a moderate one. Arsenic should not usually be given in acute and inflammatory forms of psoriasis. Arsenic acts slowly. Where in a case of psoriasis it is going to do good, improvement generally begins to be shown after two or three weeks; but to get the full benefit of the drug it must be given for several months, and its administration should be continued for several months after the eruption has disappeared.

The best form in which to administer arsenic is, in the great majority of cases, unquestionably that of "Fowler's solution"—Liquor Potassii Arsenitis—of which five drops contain about one-twentieth of a grain of arsenious acid, the average dose. The medicine should never be given in drops, as mistakes are likely to occur. A very good formula, and the one almost always employed by the writer, is the following: ℞. Liq. potas. arsenit., Gm. 8 (ʒ ij.); vini ferri, ad Gm. 128 (f ℥ iv.). M. Sig.—Teaspoonful three times a day, after meals. The dose here is four minims. The amount may be gradually increased, say, every three days, until an effect upon the eruption becomes perceptible, or until the limit of tolerance is reached.

Sometimes it is desirable to give the arsenic in pill-form: ℞. Pulv. acidi arseniosi, Gm. .14 (gr. ij.); pulv. piperis nigræ, pulv. glycyrrhizæ rad., āā Gm. 3 (℈ij.). M. et div. in pil. No. xl. Sig.—One, after meals. Or, occasionally, powders may be preferred: ℞. Pulv. acidi arseniosi, Gm. .14 (gr. ij.); pulv. sacch. lactis, Gm. 10 (gr. cl.). M. in chart No. xl. div.

But neither pills nor powders are as effective as Fowler's solution, and the writer rarely prescribes them unless forced to do so by circumstances.

Various other specifics have been recommended for psoriasis at different times; tar, carbolic acid, turpentine, phosphorus, and iodide of potassium may be mentioned. None of these, however, has stood the test of time.

Some cases of psoriasis require, instead of the specific treatment, one directed against the patient's general condition. In debilitated cases, cod-liver oil, iron, the hypophosphites, etc., are useful. In thin, worn-out women, as nursing mothers, where the attack has come on during lactation, iron is imperatively called for. Next to iron is cod-liver oil, and these remedies occasionally succeed where arsenic fails. In acute inflammatory cases, diuretics are occasionally of service. Acetate of potassium, in half-drachm doses, may be given three or four times a day, in a wineglass of water. The alkaline mineral waters are also of service.

The local treatment of psoriasis is of more or less importance, according to the nature of the case. Where the lesions are few, small, and widely disseminated, and there are no disagreeable subjective symptoms, local treatment is inconvenient, and need not be employed. Where, however, there are a few large patches, or where the eruption is situated on some conspicuous part of the person, or gives rise to annoying burning or itching, local treatment is required, and will be found advantageous. If there are scales, these should first be removed by rubbing with sapo viridis and hot water, or by the use of a hot-water bath. If the patches are few in number, large, and very scaly, the following solution, well rubbed in, will remove the scales readily, and give an opportunity for making healing applications: ℞. Acid. salicylici, 4 Gm. (ʒ j.); alcoholis, 64 Gm. (f ℥ ij.). This is especially useful upon the scalp. After the scales have been cleaned off by this means, or by means of spiritus saponis alkalinus (two parts of sapo viridis dissolved in one part of hot alcohol, and filtered) used as a shampoo, an oil composed of one drachm of oil of cade to the ounce of oil of almonds or alcohol may be well rubbed in with the aid of a brush. On the edge of the scalp and about the face the best ointment is that of ammoniated mercury, twenty to forty grains to the ounce.

Where it is desirable to get rid of the scales and patches in the most rapid manner possible, chrysarobin is the best application. An ointment of half a drachm to a drachm to the ounce is very efficient, and will remove a patch in a few days, leaving a white spot of skin surrounded by a purplish areola in its place.

There are strong objections to the use of chrysarobin, however. It discolors everything with which it comes in contact, dyes the hair orange-yellow, and spoils the clothes. It cannot be used on the scalp or about the eyes and cheeks, because it induces inflammation there, and it cannot be trusted in the hands of most patients, because, unless used cautiously, it may inflame the skin wherever used. G. H. Fox has suggested the following solution, which is effectual, though decidedly less so than the ointment, and which saves the smearing which renders the chrysarobin ointments so annoying and disagreeable: ℞. Chrysarobin, 4 Gm. (ʒ j.); ætheris et alcoholis, āā q. s.; collodii, 32 Gm. (℥ j.). M. Rub up the chrysarobin with a little alcohol and ether and add to the collodion. It forms a sort of emulsion, which should be shaken before using. By the aid of a camel's-hair pencil in the cork this may be painted over the affected patches after removal of the scales. When it dries it will not come off on the clothes, which is a great advantage.

Next to chrysarobin in activity comes pyrogallic acid. This may be used in ointment, a drachm to the ounce. It is not so effectual, but is much more cleanly, although it leaves a blackish stain. It should not be employed over a very large area at once, for fear of absorption.

Preparations of tar have been used from time immemorial in the treatment of psoriasis. They are particularly useful when there is a good deal of itching. Pix liquida and oleum cadinum are the forms most commonly employed, either in ointment or dissolved in alcohol in the proportion of one or two drachms or more to the ounce. The solution known as "Tinctura Saponis cum Pice" is a useful application; it is composed of equal parts of sapo viridis, pix liquida, and alcohol. Wilkinson's ointment is also useful, owing its virtues partly to the sulphur which it contains. The formula for it is as follows: ℞. Olei cadini, flor. sulphuris, āā 12 Gm. (ʒ iij.); saponis viridis, adipis, āā 24 Gm. (ʒ vj.); cretæ, 1.7 Gm. (gr. xxvj.). These preparations should be rubbed firmly into the diseased patches, once or twice daily.

In very severe or extensive psoriasis, baths, with the inunction of bland oils and fats, are better than any of the applications mentioned. Tar may be used at times, but with caution.

The *prognosis* of psoriasis, so far as the individual attack is concerned, is in medium and mild cases usually favorable. But the disease is prone to relapse, and the patient should be warned that while the attack can be cured, the affection is liable to return, and that no treatment, however well directed, will surely prevent the disease from coming back. Severe cases especially, when almost the entire surface is covered with the disease, are often rebellious to all treatment.

Arthur Van Harlingen.

PTERYGIUM (πτερυξ, a wing). A circumscribed hypertrophy of the conjunctiva and subconjunctival tissue, triangular in shape, more or less vascular, and exhibiting a tendency to encroach upon the cornea. The apex of the growth is always turned toward the centre of the cornea, the base toward the equator of the eye. Its usual location is to the nasal side of the cornea, over the region of attachment of the tendon of the rectus internus to the sclerotic; exceptionally it occurs to the outer side of the cornea, and still more rarely above or below it. It usually develops very slowly, and many months, or even years, may elapse without its extending far enough toward the centre of the cornea to impair

vision. It is rarely met with in children, and is more prevalent in tropical than in temperate countries. The apex of a pterygium not infrequently reaches, but rarely passes beyond, the centre of the cornea. The writer has met with one case, however, in which a pterygium of unusually large size, starting from the nasal side of the eye, grew entirely across the cornea to its external margin. The other eye of the same individual (a woman, advanced in years) also exhibited a large pterygium, which had already passed beyond the centre of the cornea. So long as the growth is confined to the conjunctiva and the periphery of the cornea it usually causes little or no inconvenience, but as soon as it encroaches upon the area of the pupil it greatly impairs vision, not only because, being opaque, it obstructs the passage of light into the eye, but because the curvature of the corneal surface about its apex is so altered as to produce a high grade of irregular astigmatism.

In the text-books of forty or fifty years since, four or five varieties of pterygium are described. There seems to be little reason, however, for making even the two varieties which more recent authors mention; although, as some pterygia are thin and scantily supplied with blood-vessels while others are thick and vascular, there is some warrant, perhaps, for calling the former variety *pterygium tenue*, and the latter *pterygium crassum*. The *pterygium pingue* of the older authors is the pinguecula of the present day, which is no longer regarded as a variety of pterygium; while their *pterygium malignum* was, as its name implies, simply a malignant growth involving the cornea, which at the present day we would, of course, not think

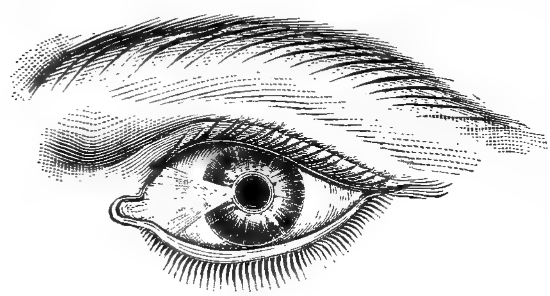

FIG. 3129.—Pterygium.

of confounding with true pterygium. It is possible for several pterygia to develop upon the same eye, advancing upon the cornea from different directions, and cases of this character have been reported, but they are of extreme rarity.

The question of the *pathogenesis* of pterygium has, from time to time, been discussed, and various theories have been suggested to account for its development and growth. None of those so far advanced seems, however, to be satisfactory. Arlt, some years ago, suggested that the starting-point of pterygium is the existence of a superficial ulcer or abrasion at the margin of the cornea, to which the neighboring swollen conjunctiva becomes adherent, and that the dragging and irritation which results from this is the cause of its subsequent growth; and this theory has met with very general acceptance. It takes no account of the fact, however, that ulcers and abrasions of the cornea are not especially frequent upon its nasal margin, while pterygium, as we have seen, occurs only very rarely elsewhere; nor of the further fact that many cases of pterygium can be recognized as such before the apex of the growth has even reached the corneal limbus, and, therefore, before the process which is assumed to be the first step in its development has taken place. That pterygium is produced in this manner, in exceptional cases, there is no doubt; but this fact was recognized before Arlt's day—notably by W. Lawrence,[1] who refers to cases of pterygium following purulent ophthalmia, in which the conjunctiva from the upper part of the globe had become adherent to an ulcer upon the lower part of the cornea.* He distinguishes, however, between these cases and true pterygium, and mentions his suspicion that the pterygia said to have been seen on the upper part of the globe were cases of this character, as he had never seen true pterygium in this situation.

It is manifest that any theory which would satisfactorily account for the development of pterygium must also account for the fact that it occurs in so large a proportion of cases to the nasal side of the cornea. This Arlt's theory fails to do; for it is beyond question that if pterygium were, as a rule, produced in the way he describes, we should find it encroaching upon the cornea from every possible direction, and not much more frequently from one direction than from another. The theory more recently proposed by Poncet, that pterygium is a parasitic disease, and that its advance over the cornea is due to the presence of microbia—parasitic "vibriones," which he finds beneath the head of the pterygium, and which are supposed to tunnel their way under the corneal epithelium—fails equally in this respect; and, besides, the precedent ulcer which he regards as the starting-point of the process, and as essential to it, has not been clinically demonstrated, but, rather, assumed to have been present.

In endeavoring to reach a satisfactory explanation of the origin of pterygium, it is important that we should bear in mind the fact (which seems usually to have been lost sight of) that in its incipient stage the growth does not, as a rule, involve the cornea at all, but is confined to the sclerotic conjunctiva. As Lawrence very aptly puts it: "It begins with the appearance, in the conjunctiva scleroticæ, of a few vessels rather larger than natural, and running from behind forward nearly parallel to each other. After some time the membrane is found, on accurate inspection, to be a little raised, but the surface is smooth and entire. It gradually assumes the triangular shape, the basis extending toward the circumference of the eye, while the apex passes over the junction of the sclerotica and cornea and advances on the latter."[2] This description of the development of pterygium entirely agrees with the writer's own observations, and it suggests at once that the primary cause of pterygium is to be sought for elsewhere than in diseased conditions of the cornea.

It has long been taught that the development of pterygium is favored by conditions which bring about persistent hyperæmia of the conjunctiva, as, for example, when the eyes are exposed to the heat of a tropical sun, as in long sea-voyages, or to the heat from furnaces, as is the case with stokers and founders, or to the irritant action of dust and vapors, as in mills and other manufacturing establishments; and the evidence in favor of this view is much too strong to be put aside. Assuming, then, that hyperæmia of the conjunctiva is an important factor in the production of pterygium, are there reasons why this condition should occur especially where pterygium usually makes its appearance—to the nasal side of the cornea? The writer does not hesitate to answer this question affirmatively. He is not aware that it has been suggested, heretofore, that the recti muscles of the globe have anything to do with the production of pterygium; but it seems to him highly probable that such is the case. In the first place, it is well known that it is an extremely rare occurrence to meet with a pterygium which does not lie directly over the insertion of one of these muscles—they scarcely ever approach the cornea except in an exactly horizontal or vertical direction. Again, the vascular system of the conjunctiva in the neighborhood of the corneal border (anterior conjunctival vessels of Van Woerden) is so intimately connected with that of the recti muscles, through branches derived from the anterior ciliary arteries, that the possibility of the blood-supply of the former being influenced by that of the latter can scarcely be doubted. There is nothing improbable, therefore, in the assumption that the determination of blood to the recti muscles may bring

* The writer has also met with a case of this character as a result of gonorrhœal conjunctivitis. Only the apex of the pterygium, however, was adherent to the cornea, and a probe could be passed between the corneal surface and the body of the pterygium.

about a hyperæmic condition of the overlying conjunctiva, and that this condition, as we have seen, may in time lead to the development of pterygium. Moreover, it is manifest that the recti interni muscles would be likely to exert a much more decided influence in this respect than any of the others; for they are not only the largest of the straight muscles, and the ones which perform by far the greatest amount of work, but their attachment to the sclerotic is considerably nearer the corneal border, and they are, therefore, more intimately connected with the conjunctiva. Thus the location of pterygium to the nasal side of the cornea is at once explained.

In support of this view as to the origin of pterygium, which, to the writer, seems at least to be more satisfactory than those which have as yet been offered, it may be mentioned, as a matter of observation, that persons who have pterygium not infrequently complain that the pterygium itself, and the conjunctiva in its neighborhood, become bloodshot when the eyes are much used in near work. How far insufficiency of the internal recti muscles may influence the development of pterygium is a question which at once suggests itself, and which calls for investigation. Although the writer has, as yet, but little evidence to offer bearing upon this point, he is disposed to think that this and other disturbances in the muscular balance of the eye play an important rôle in the pathological process under consideration. It remains to be added that pterygium sometimes has its origin in traumatic lesions of the conjunctiva, as, for example, to cite from the writer's experience, a burn from a scale of hot iron or from partially slaked lime splashing into the eye.

In regard to the *treatment* of pterygium, little is to be expected except from operative interference. In its incipient stage, however, its growth may possibly be arrested by correcting, by means of glasses, any error of refraction or any muscular defect which may exist; and, even when it has reached a more advanced stage, its development may, perhaps, be favorably influenced in this way. So, too, after any operation which may be resorted to for its cure, the good which glasses may do by lessening the tendency to a recurrence should not be lost sight of. It should be borne in mind that the asthenopic symptoms, of which persons suffering with pterygium often complain, are much more likely to be due to some error of refraction or muscular defect than to the mere presence of the growth. The propriety of resorting to operative treatment will be determined by several considerations: If the pterygium be confined to the conjunctiva, it may be advisable to operate upon it, provided it be narrow and well defined. If, on the contrary, it be broad and ill defined, it will be wiser not to interfere with it, as the condition and appearance of the eye after the operation will probably not be better than before. If, however, it has encroached upon the cornea, it is better, as a rule, to operate, because, as has been said, it usually advances farther and farther upon this membrane, and, as it does so, it produces such changes in its structure as to leave behind a permanent opacity, even when the growth is most carefully removed. Patients will frequently assure the surgeon that the pterygium is not growing, and that for months or years it has made no progress; but their testimony upon this point is not always to be relied upon, and to prevent the possibility of the sight eventually becoming impaired, unnecessary delay in resorting to operation should be avoided.

The operative procedures which have been suggested for the cure of pterygium are numerous. Until a comparatively recent period, excision was the only operation which was in vogue. The results obtained by this method were, however, by no means uniformly successful, the removal of the growth, as it was commonly practised, being not infrequently followed by its recurrence. In consequence of this, various substitutes for this operation were proposed. For example, Des Marres suggested transplantation of the pterygium; Szokalski its destruction by strangulation, while Knapp introduced a modification of the former, and Galezowski of the latter, procedure. Pagenstecher recommended that the growth should simply be dissected from its corneal, and in part from its sclerotic, attachments, and then be allowed to atrophy, the edges of the conjunctival wound being united beneath the partially detached pterygium by means of sutures. Arlt, also, preferred a method essentially the same as that of Pagenstecher. In Des Marres's operation the pterygium is detached from the cornea and sclerotic quite up to its base, and is then inserted into an incision made in the conjunctiva near the lower edge of the cornea, where it is retained by sutures. Knapp's modification of this method, applicable to cases in which the pterygium is of large size, consists in splitting the pterygium longitudinally, after having removed its corneal portion, and inserting the upper half in an incision made in the conjunctiva above its base, and the lower half in one made below. He also unites the edges of the conjunctival wound by sutures, and, to facilitate this, separates the conjunctiva from the subjacent tissue above and below the wound. In Szokalski's operation the strangulation is accomplished by passing two needles, which have been threaded with the opposite ends of a fine silk ligature, beneath the pterygium, one near its apex, the other near its base, and then, after cutting out the needles, by tying together the ends of the three threads which are thus left in position, so as to cut off its vascular supply near its base, near its apex, and from its sclerotic surface. Galezowski, after dissecting up the pterygium, "takes a thread, armed at each end with a curved needle, and pierces the apex with both needles, so as to include it in a small loop. Then turning the needles inward, he brings them out at the base of the growth, one near the upper and the other near the lower margin. The two ends are then tied in a tight knot, and thus the apex of the pterygium is turned inward toward the base, and the latter is strangulated by the knot." It is claimed for each of these procedures that a recurrence of the growth is less apt to happen than when simple excision is practised.

The operation of excision has, in the writer's experience, yielded such satisfactory results that he has not been tempted to make trial of any of these newer methods. The end which they all accomplish seems to him to be the same—to minimize the loss of conjunctival tissue, and this is, undoubtedly, a most important thing; but, if the excision be performed as it should be, the loss of tissue is insignificant. Although the ill effects of a too free excision of the growth were long ago pointed out, especially by Scarpa, the writer is inclined to think that the poor results which many have obtained from this operation are due to unnecessary loss of conjunctival tissue. Even when but little more than the apex of the growth is removed, the gap which is left in the conjunctiva is of considerable size, and when the whole pterygium is cut off, the size of the gap which results, owing to the retraction of the conjunctiva, is surprising. Under such circumstances the healing process is slow and difficult, and ultimately a prominent vascular cicatrix is apt to be left, which is as unsightly, and as likely to cause trouble, as the pterygium itself.

Since the employment of cocaine in ophthalmic surgery the removal of pterygium has been rendered much easier, as the operation is now entirely painless. The method of operating which the writer has adopted, and which, as has been said, has yielded satisfactory results, being very rarely followed by a return of the pterygium, is as follows: The eye having been brought under the influence of cocaine, and the patient being seated in a chair, the operator standing behind, a stop-speculum is introduced. The growth is then seized near its apex with forceps, and with an iridectomy-knife, which is but slightly bent, is cleanly dissected from the cornea, especial care being taken to detach its margins from the corneal limbus. Its more loose attachments to the sclerotic are also separated for a short distance (2 or 3 mm.) from the corneal margin. Then, with a pair of slender scissors, curved on the flat, the whole of the corneal and a very small part of the conjunctival portion of the growth is removed at a single cut. If decided traction is made with the forceps upon the detached portion of the growth while the scissors are being used, and if the latter are pressed

against the sclerotic, a very much larger piece of the pterygium will be removed than is desirable. Only very slight traction, therefore, should be exerted, and in using the scissors (the points of which should be turned toward the base of the growth) it should be borne in mind that we are more apt to remove too much than too little tissue. A single stitch of fine black silk will suffice to close the conjunctival wound, and, unless more tissue has been sacrificed than is necessary, will bring its edges together without undue traction. The closure of the wound in this way hastens the healing process, and the removal of the stitch, on the second or third day, as may seem more desirable, can be accomplished without pain by the instillation of a drop or two of cocaine. The dressing most acceptable to the eye is a linen cloth wet with cold water, which may be applied at intervals for a few days. A collyrium of boracic acid (gr. v.-x. to aq. destill., ℥ j.) should then be prescribed, to be used three or four times a day, as it soothes the eye, lessens the secretion, and helps to subdue the inflammation. Should there be much ciliary irritation from inflammation of the corneal tissue, atropine is indicated, while, on the other hand, if there is considerable conjunctival secretion, without ciliary irritation, a very little sulphate of zinc (gr. $\frac{1}{4}$–$\frac{1}{2}$ to ℥ j.) or alum (gr. ss.–j. to ℥ j.) may be added, with benefit, to the boracic-acid solution. The patient should be warned that the improvement in the appearance of the eye will be slow, else he may suppose the operation has not been successful, and may mistake the vascularity which remains for some time about the former site of the pterygium for a return of the growth. When the pterygium has encroached upon the cornea, he should also be made to understand that after its removal a more or less perceptible opacity will remain upon the surface of this membrane. Should this opacity involve the central portion of the cornea, which in exceptional instances is the case, an iridectomy may be necessary in order to obtain a pupil behind a part of the cornea which is clear.

Samuel Theobald.

PTOMAÏNES—POST-MORTEM ALKALOIDS. HISTORICAL.—The name *Ptomaïne*, written by some recent German authors *Ptomatine* (πτῶμα = that which is fallen, a corpse), was first suggested by Selmi, in 1875, to designate substances obtained from putrefying organic material and possessed of the general properties which characterize the vegetable alkaloids, and which were formerly considered as peculiar to those substances.

It had been observed in the first half of the last century that certain articles of food, when in a condition of incipient putrefaction, not sufficiently advanced to awaken suspicion by the liberation of odorous products, caused violent symptoms of poisoning and death in the human subject. It was also a matter of early experience that serious results, and even death, might follow inoculation with the juices of the uninjected cadaver before putrefaction had progressed to the stage in which putrid gases are given off.

The earlier observers advanced different theories concerning the nature of the poisonous substances in these cases. The earliest of these (1789) accounted for the poisoning by the supposition of an admixture of mineral poison. Emmert (1815) sought to show the formation of hydrocyanic acid during modified putrefaction. Rumpelt, Berres, and Saladin considered the poisonous qualities of certain sausages to be due to the formation of empyreumatic products related to creasote. The poisonous qualities of sausages were attributed by Boullay to the use of poisonous vegetables by mistake for the herbs commonly employed in their manufacture, and by Wunderlich to a diseased condition of the animals which yielded the meat. Kerner (1820) considered that picric acid (Welther's bitter) was the poisonous agent. Witting, Kerner, and Buchner thought it was a product of decomposition of the fats, an empyreumatic fatty acid, or acroleïn. Weiss and Liebig (1824) considered that the poison acted chemically upon the blood "by catalysis," and was "analogous to the typhic miasm."

The first to suggest the probability of the formation of an alkaloidal poison during putrefaction seems to have been Kastner (*Arch. f. Gesam. Naturlehre*, Bd. i. (1824), 448, 488; Bd. ii., 499), who advanced the hypothesis that poisonous sausages contained an "alkaloid of decay" (*Moderalkaloid*) combined with an organic acid.

In 1852, Schlossberger, in an exhaustive paper upon the sausage-poison (*Arch. f. Physiol. Heilk.*, Ergänz hft., 1852) supposes "the poisonous substances occurring in sausages and cheese to be organic bases, which have their origin in the decomposition (*Entmischung*) of the proteïn materials rich in nitrogen, under certain conditions." He supports this hypothesis by the following observations: 1st, When ammonia is produced in considerable amount by the decomposition of animal or vegetable substances, it is accompanied by volatile bases (Stenhouse); 2d, by the action of dilute potash upon poisonous sausages, much ammonia, "accompanied by a peculiar, repulsive odor," is given off; 3d, the physiological action of the putrid poison is very similar to those of the then known volatile alkaloids nicotine, coniïne, sparteïne, and to those of the artificial amide, imide, and nitrile bases of Hofmann; 4th, one of these bases, trimethylamine, is contained in herring-pickle. Schlossberger also suggests that fixed as well as volatile alkaloids are probably produced during putrefaction.

Four years later (1856) Panum was probably the first to isolate ptomaïne, in an impure state however (*Bibl. for Laeger*, 1856; *Schmidt's Jahrb.*, 1859, ci., 213; *Virchow's Arch.*, 1874, lx., 328–352). This substance was designated by Panum as the "extractive putrid poison." It is described as being soluble in water, from which it is precipitated by alcohol; capable of extraction from putrid meat; and not identical with known odorous products of putrefaction. It is capable of withstanding a boiling temperature, evaporation, and the influence of absolute alcohol—conditions inconsistent with the presence of lower organisms. Panum further states that it is comparable to the poison of serpents, curare, and the vegetable alkaloids in its action on the economy.

During the years 1859 to 1868, the subject appears to have remained in the condition in which it was left by Panum, although, in 1866, Hemmer, Schwenninger, and Von Raison published dissertations upon the putrid poison. In the same year, Bence Jones and Dupré obtained from animal matter a substance which formed precipitates with the general reagents for the alkaloids then known, and whose solution exhibited a blue fluorescence. To this substance they gave the name of "animal chinoidine."

In 1868, Bergmann and Schmiedeberg obtained a small quantity of a crystalline substance, which was poisonous to dogs and frogs, and to which the name *sepsine* was applied.

In 1869, Zuelzer and Sonnenschein obtained from cadavers a crystalline substance having physiological actions similar to those of atropine.

The discovery in cadaveric matter of alkaloids which could not be identified with any then known led Selmi to a series of experiments which enabled him to identify and characterize those ptomaïnes with greater precision. His first publication upon the subject was a paper read before the Academy of Sciences of Bologna, January 25, 1872. Since that time the contributions of Selmi and of his followers—Morrigia and Battistini, Trottarelli, Raffaele, Ziino, Albertoni and Lussana, Paterno, Spica, Brugnatelli and Zenoni, Bocci, Guareschi and Mosso, and Monari—have been voluminous and important.

Attempts have been made by Arm. Gautier and his followers to appropriate the credit due to Selmi (Gautier: "Ptomaïnes," p. 6, Paris, 1886), on the strength of unpublished experiments and a vague statement made in a work printed in 1874.

The most important of the numerous recent monographs upon this subject are those of L. Brieger ("Ueber Ptomaïne," i., 1885; ii., 1885; iii., 1886).

Nencki ("Ü. d. Zersetz d. Gelatine," etc., Bern., 1876) was the first to determine the chemical composition of a ptomaïne, and thus clearly to establish the nature and relations of these substances.

PTOMAÏNES FORMED DURING PUTREFACTION OF MUSCULAR TISSUE AND INTERNAL ORGANS OF MAMMALS.—*Cadaveric Alkaloids.*—The nature of these bases varies with those conditions which have been known to modify the progress of putrefactive changes, viz.: 1, the nature of the putrefactive ferment—*i.e.*, according to existing views, the species of bacterium; 2, the kind of albuminoid or gelatinoid undergoing putrefaction; 3, the temperature; 4, the degree of moisture; 5, the access, or non-access, of atmospheric oxygen.

In the case of cadaveric putrefaction, as it usually occurs, when the entire body is subjected to decomposition, it is also probable that the nature of the ptomaïnes produced is influenced by the results of the simultaneous changes which the carbohydrate and fatty constituents undergo.

As the process of putrefaction is gradual and progressive, different basic substances are produced at different stages. Therefore, a base obtainable in considerable amount from a body during the first days of putrefaction will have more or less completely disappeared at a later stage, when other bases, not previously present, will have made their appearance.

For our present knowledge of the composition of the cadaveric alkaloids we are largely indebted to Brieger (*loc. cit.*).

The numerous substances whose reactions and physiological properties have been described by Selmi and his followers probably consisted, in most cases, of the alkaloids mentioned below, mixed with greater or less quantities of other substances, or of their more or less pure products of decomposition. The frequent variations in chemical and physiological action of the materials operated upon by these observers are due to the fact that they consisted of residues whose purity was not assured by crystalline form or by chemical analysis. It is also probable that the number of existent ptomaïnes is by no means as great as an examination of the literature of the subject would lead one to suppose, although it is certain that many more will be added to those whose composition and character have been already determined.

Immediately after death the most unstable of the constituents of the body, *lecithin*, is decomposed into distearylglycerophosphoric acid and choline.

Choline, $C_5H_{15}NO_2$, is a syrupy, highly alkaline liquid, soluble in all proportions in water, whose chloride crystallizes in colorless, highly deliquescent needles, very soluble in water. With platinic chloride it forms a readily soluble double salt, crystallizing in orange-red prisms. With auric chloride it forms a crystalline double salt, almost insoluble in cold water, soluble in hot water.

This base was originally obtained by Strecker from ox-bile, in 1849, and was subsequently shown by Diakonow to be a constituent of *lecithin*. It was also obtained by Gobley from yolks of eggs, and has since been found to be widely disseminated in animal tissues. It has been considered by many chemists as identical with the *neurine* which constitutes a large portion of the protagon of Liebreich. The investigations of Baeyer, however, have shown that the two bases are distinct. *Choline*, obtainable from bile and lecithin, is identical with the synthetic trimethylhydroxethylene ammonium hydrate, $\left.\begin{matrix}(CH_3)_3\\(C_2H_4OH)\end{matrix}\right\}N,OH$, while *neurine* is trimethylvinyl ammonium hydrate, $\left.\begin{matrix}(CH_3)_3\\(C_2H_3)\end{matrix}\right\}N,OH$.

Choline is non-poisonous, except in large doses, which produce effects similar to those of muscarine.

As putrefaction advances, choline gradually disappears, its place being taken by trimethylamine, $(CH_3)_3N$, produced by its decomposition. After seven days, choline is no longer present.

Within three days after death another base makes its appearance:

Neuridine, $C_5H_{14}N_2$(?), a diamine discovered by Brieger. The chloride crystallizes in long needles, resembling urea, and is very soluble in water, insoluble in alcohol, ether, chloroform, petroleum-ether, benzol, and amyl-alcohol. If, however, it be accompanied by other animal substances, it is dissolved in greater or less quantity by the above solvents, and hence may be present in the extracts obtained by the Stas-Otto and Dragendorff methods. Solutions of the chloride give the following reactions with general reagents: Phosphotungstic acid, white, amorphous precipitate, soluble in excess; phosphomolybdic acid, white, crystalline precipitate; phosphoantimonic acid, white, flocculent precipitate; picric acid, precipitate, slowly converted into yellow needles; auric chloride, crystalline precipitate. With other usual reagents, nothing. With platinic chloride it forms flat needles of a double salt, readily soluble in water, from which solution it is precipitated by alcohol. The picrate is crystalline, and insoluble in water.

The free base is a gelatinous substance which decomposes even during evaporation of its solution. Its odor resembles that of spermatic fluid. It is insoluble in absolute alcohol and in ether, difficultly soluble in amyl-alcohol, readily soluble in water. It forms white precipitates with mercuric chloride, and with basic and neutral lead acetate. When heated with caustic soda it yields dimethylamine and trimethylamine, a decomposition which shows it to be not identical with amylendiamine, with which it is isomeric.

Neuridine is produced in greatest abundance in putrid intestines, while glandular organs yield but little under like conditions. It is no longer present after fourteen days. It is also found during putrefaction of fish, cheese, and gelatine, and is obtainable from fresh eggs and human brain-tissue.

When pure, neuridine is perfectly non-poisonous; but when contaminated by other putrefactive products it exerts a poisonous action.

On the third day of slow putrefaction, traces of another alkaloid are detectable, which increases in amount as the choline and neuridine disappear, and is accompanied by trimethylamine:

Cadaverine, $C_5H_{14}N_2$, a base identical with the pentamethylendiamine, $NH_2\text{–}CH_2\text{–}CH_2\text{–}CH_2\text{–}CH_2\text{–}CH_2\text{–}NH_2$, of Ladenburg, is a thick, transparent liquid, having a very disagreeable odor, somewhat resembling that of coniïne; boils at 175° C.; fumes, and absorbs carbon dioxide rapidly when exposed to air, being converted into a crystalline compound. Its chloride is crystalline, deliquescent, readily soluble in water and in dilute alcohol, but insoluble in absolute alcohol and in ether. With platinic chloride it forms crystals, resembling those of platinum-ammonium chloride, which are difficultly soluble in water.

The reactions of cadaverine chloride with the general reagents are as follows: Phosphotungstic acid, white precipitate, easily soluble in excess; phosphomolybdic acid, white, crystalline precipitate; bismuth-potassium iodide, red, crystalline needles; iodine in potassium iodide, or in hydriodic acid, brown crystals; picric acid, yellow needles; potassium chromate and sulphuric acid, red-brown, evanescent precipitate; ferric chloride and potassium ferricyanide, faint-blue color. The free base gives distinct blue with ferric chloride and ferricyanide.

Putrescine, $C_4H_{12}N_2$, is another base found by Brieger to accompany cadaverine. It is a clear, rather thin liquid of a disagreeable odor, resembling that of the pyridine bases; boils at 156°–157° C.; capable of distillation unchanged; absorbs carbon dioxide energetically from the air. Its chloride forms long, clear, transparent needles, is not hygroscopic, is readily soluble in water, sparingly soluble in dilute alcohol, and insoluble in absolute alcohol. The reactions of the chloride are: Phosphotungstic acid, white precipitate; phosphomolybdic acid, yellow precipitate; potassium iodhydrargyrate and bismuth-potassium iodide, amorphous precipitates, becoming crystalline; iodine in potassium iodide, or in hydriodic acid, brown, crystalline precipitates; picric acid, well-formed, broad, difficultly soluble needles. The

chloroplatinate of putrescine forms six-sided plates, as does also the chloraurate. Putrescine is not a homologue of cadaverine, but is probably either dimethylethylene-diamine or methylethylmethylenediamine.

Saprine, $C_5H_{16}N_2$, is still another base, formed under similar conditions with cadaverine, and distinguished from it by a greater solubility and different crystalline form of its chloroplatinate, by the absence of a compound with auric chloride, by the permanence of its chloride in air, and by its failure to give the reaction with potassium chromate and sulphuric acid.

Neither of the above-mentioned alkaloids is possessed of toxic qualities, with the exception of choline, and that only when administered in large quantity. It is probable that the poisonous effects produced by inoculation with cadaveric matter during the earlier days of putrefaction are due to substances such as the peptotoxine mentioned below and produced along with the peptones, which are among the first products of putrefaction.

Brieger obtained from human cadaveric matter two alkaloids possessed of actively poisonous qualities:

Mydaleïn, observed in small amount after seven days of free exposure to air, and increasing in amount up to three weeks. The amount of this base obtained was insufficient to determine its composition, further than that its chloroplatinate contains Pt., 38.74; C., 10.83; H., 3.23 per cent.; from which the inference is drawn that it is a diamine, closely related to the ptomaïnes above described. The chloride crystallizes with great difficulty, is very hygroscopic, and gives the following reactions: Platinic chloride, microscopic needles arranged in bundles; auric chloride, oily drops; phosphomolybdic acid, yellow, amorphous precipitate; phosphotungstic acid, white precipitate, soluble in excess; potassium iodhydrargyrate, yellow, oily drops; bismuth-potassium iodide, iodine in potassium iodide, and iodine in hydriodic acid, dirty-brown, oily drops; picric acid, a yellow oil; ferric chloride and potassium ferricyanide, immediate, intense blue color.

This alkaloid, administered to rabbits and guinea-pigs in very small quantity by hypodermic injection, produces the following effects: The lower lip becomes moist, the nasal and lachrymal secretions become very abundant, the pupils are dilated and insensible to light, the vessels of the ear are injected, the rectal temperature rises 1° to 2° C., the respiration and cardiac action are at first accelerated, the animal exhibits a tendency to sleep, and the peristaltic action of the intestines is augmented. The symptoms gradually abate and the animal recovers.

With larger doses (less than five milligrams=$\frac{8}{100}$ grain), administered to guinea-pigs, the action is intense and terminates in death. The secretion of organs provided with unstriped muscular fibres becomes very profuse. The pupils are widely dilated. There is exophthalmus. The animal falls; the posterior extremities being first paralyzed, then the anterior; and there occur fibrillar spasms of various groups of muscles. Sometimes the animal springs up and immediately falls, making faint motions of the legs. The body-temperature falls gradually; the movements become more and more faint, and the animal dies. The heart is arrested in diastole, and the intestines and bladder are found contracted after death.

Five milligrams of the chloride administered to a small cat caused death. There is immediate dilatation and insensibility of the pupils; the lachrymal secretion is very abundant. Profuse diarrhœa and vomiting of whitish masses follow. The secretion of saliva and perspiration become very profuse. The animal becomes lethargic, then suddenly springs up with accelerated respiration, and immediately sinks back. The secretion of alkaline, ropy saliva continues to increase. Violent convulsions occur. Soon the posterior extremities become paralyzed, afterward the anterior, while the abdominal and dorsal muscles contract spasmodically, and the animal lies with the head pressed down and the extremities extended. The respiration, at first very frequent, becomes slow and labored. The animal dies in a state of sopor. After death the heart is found to be arrested in diastole, and the intestine, whose mucous membrane is somewhat injected, contains a thin, fluid secretion.

By the putrefaction of muscular tissue in the presence of water, at the temperature of incubation, for five to six days, Brieger obtained, besides neuridine, an alkaloid possessed of distinctly poisonous characters:

Neurine, $C_5H_{13}NO$ = Trimethylvinyl ammonium hydrate, $\left.\begin{matrix}(CH_3)_3\\(C_2H_3)\end{matrix}\right\}$ N,OH (see choline, *supra*). A base whose chloroplatinate crystallizes in fine, well-defined octahedra, almost insoluble in water; and whose chloraurate crystallizes in flat prisms. Its chloride behaves with general reagents as follows: Phosphomolybdic acid, white, crystalline precipitate, insoluble in excess; phosphotungstic acid, nothing; phosphoantimonic acid, voluminous, white precipitate; potassium iodhydrargyrate, voluminous, yellowish-white precipitate; bismuth-potassium iodide, amorphous, red precipitate; cadmium-potassium iodide, white precipitate; iodine in potassium iodide, iodine in hydriodic acid, amorphous, brown precipitates; tannic acid, voluminous, dirty-white precipitate; mercuric chloride, granular, white precipitate.

When administered to frogs, mice, guinea-pigs, rabbits, and cats, hypodermically, the chloride of this alkaloid produces symptoms closely resembling those caused by muscarine. Cats are more susceptible to its action than the other mammals experimented on.

The administration of the poison to rabbits is soon followed by marked moisture of the nostrils and lips. Movements of mastication follow, accompanied by the discharge of copious, thick, tenacious fluid from the angles of the mouth. There is profuse secretion of saliva, which is at first thick and viscid, then thin and alkaline. The increased secretion of saliva continues until the termination of the poisoning, and varies in degree with the magnitude of the dose. Subsequently there is increased secretion from the Schneiderian mucous membrane and the lachrymal glands, the latter of short duration. The respiratory movements are at first more frequent and deeper than normal; the extraordinary respiratory muscles are brought into action, the head thrown back, and the nostrils dilated. These symptoms of dyspnœa alter in character as death approaches, in that the movements become irregular, superficial, and less frequent. The heart's action immediately after the injection is accelerated, so that the pulse cannot be counted. In a short time it becomes slower, and diminishes constantly in frequency. The pulsations are at first very strong, but subsequently become progressively weaker until the heart is arrested in complete diastole. The heart's action continues after cessation of respiration. Section of the vagi has no influence, and the heart responds to artificial stimuli. Occasionally contraction of the pupils occurs, an effect which almost always follows an application of a strong solution of the poison to the eye. Powerful peristalsis is an early symptom, causing an uninterrupted voiding of matters, at first consistent, subsequently watery. Ejaculation and dripping of urine also occur. If the abdomen be opened at this stage, tetanic contractions of greater or lesser portions of the intestine are seen. The spleen is also strongly contracted. Only when lethal doses are given do strong clonic convulsions occur, in which the animal soon dies. These convulsions are partially controlled by artificial respiration, but they soon recur. Locomotion is interfered with, the posterior extremities being first paralyzed, then the anterior, before the beginning of the convulsions. In cats there is an increased secretion of alkaline perspiration. Atropine is a powerful antidote; but atropinized animals are still subject to the action of the poison. When taken by the mouth this alkaloid produces the same effects as when administered hypodermically, but ten times the dose is required.

Mydine, $C_8H_{11}NO$, is a base obtained by Brieger from human cadaveric matter which had been in putrefaction four months at a temperature of +5° to −9° C. in closed vessels. The free alkaloid is strongly alkaline, has an ammoniacal odor, and is a strong reducing agent. Its chloroplatinate is very soluble.

Ptomaïnes.

From auric-chloride solution it precipitates metallic gold. Its picrate crystallizes in broad prisms, which fuse at 195° C. Its chloride gives a blue color with ferric chloride and potassium ferricyanide. It is non-poisonous.

From horse-flesh which had undergone four months' putrefaction, at a low temperature and without exposure to air, Brieger obtained three poisonous substances. One of these is a non-alkaloidal body, $C_7H_{17}NO_2$, probably an amido-acid, which acts upon frogs somewhat like curare. The other two are alkaloids.

Mydatoxine, $C_6H_{13}NO_2$. The free base is a strongly alkaline syrup, which crystallizes *in vacuo ;* insoluble in alcohol and ether ; decomposed by distillation. Its chloride is a colorless, thin syrup, which forms no double salt with auric chloride, and with platinic chloride a very soluble double salt, which fuses and is decomposed at 193° C.

Administered subcutaneously to guinea-pigs, the chloride of this base causes increase in the frequency of the respiration ; at first contraction, and later dilatation and insensibility, of the pupils ; and diminution of temperature, with short chills. Clonic convulsions, frequently of such intensity that the animal is involuntarily projected forward, recur at short intervals. The secretions of the salivary and lachrymal glands become more abundant. The body-temperature falls, and the respiration becomes less frequent. The ears, at first injected, become pale and cold. The extremities are paralyzed. The cardiac action becomes irregular and less frequent. Convulsions are provoked by striking upon the table supporting the animal. Shortly before death the convulsions become less strong, the extremities are extended, the animal falls upon its side and dies. After death the heart is found arrested in diastole, the intestines strongly contracted, and the bladder empty and contracted.

Methylguanidine, $C_2H_7N_3 = NH = C\begin{cases}NH(CH_3)\\ NH_2\end{cases} =$ *Methyluramine*, a colorless, highly hygroscopic, and strongly alkaline base, whose chloride crystallizes in prisms, insoluble in alcohol. The chloroplatinate crystallizes in very soluble needles. The picrate crystallizes in needles, which are sparingly soluble in water, and fuse at 192° C.

This substance is undoubtedly produced by an oxidation of creatin, to which it is closely related.

Methylguanidine is poisonous. Administered hypodermically to guinea-pigs, it causes copious diarrhœa and increased secretion of urine. The pupils are rapidly dilated and are insensible to light. The animal remains in one position, even when irritated. It soon becomes restless and seeks to move with the anterior extremities. The posterior extremities refuse to perform their function. The respiration becomes progressively deeper and more labored. The head is moved from side to side. The legs become paralyzed, and there is marked dyspnœa. The animal falls upon its side and dies, after short, general clonic convulsions. After death the heart is found in diastole, the intestine filled with fluid, the bladder contracted, the cortical portion of the kidneys hyperæmic, and the papillary portion pale.

Gautier and Étard have described two substances obtained from putrid meat, which they consider as identical with the pyridine bases *parvoline* and *hydrocollidine*, although their analyses do not accord closely with the amounts required by theory. The first of these alkaloids is an amber-colored oil, boiling at 200° C., sparingly soluble in water, and forming a very soluble chloroplatinate and a sparingly soluble chloraurate. The second is a colorless oil, having a penetrating odor, which becomes viscid and resinous when exposed to air ; absorbs carbonic acid ; boils at 210° C. Its chloraurate is soluble and readily decomposed ; its chloroplatinate, crystalline, pale-yellow, and sparingly soluble.

Ehrenberg (*Zeitschr. f. Physiol. Chem.*, 1887, xi., p. 239) obtained choline, neuridine, dimethylamine, and trimethylamine from sausages which had been the cause of serious poisoning of a number of persons, of whom three died.

Ptomaïnes from Putrid Fish.—Brieger, operating with the flesh of a species of cod (*Gadus callarias*) subjected to putrefaction with contact of air, obtained, besides neuridine, three ptomaïnes, two of which are actively poisonous :

A base, $C_2H_8N_2$, isomeric but not identical with ethylidendiamine, whose chloride crystallizes in long, brilliant needles, easily soluble in water, insoluble in absolute alcohol. It does not form a chloraurate. The chloroplatinate crystallizes in small, yellow scales, sparingly soluble in water. The chloride forms with phosphomolybdic acid a white precipitate ; with phosphoantimonic acid a yellowish-white precipitate, soluble in excess ; with bismuth-potassium iodide a red, crystalline precipitate. With other general reagents no precipitates are formed. The free base may be distilled from caustic soda without decomposition.

This base, administered hypodermically in small quantity to mice and guinea-pigs, produces in a short time increased secretions of the nasal mucus, saliva, and tears, which are subsequently temporarily arrested, to begin again later. The pupils are dilated and the globes protruded. There is marked dyspnœa, which continues until the death of the animal within twenty-four hours.

Muscarine, $C_5H_{15}NO_3$, identical with the alkaloid obtained from *Agaricus muscarius* and with that obtained synthetically from choline, forms a chloride which crystallizes with difficulty, and a chloroplatinate which crystallizes in octahedra.

This ptomaïne, administered in very small quantities to frogs, causes total paralysis and arrest of the heart in diastole. The administration of atropine to frogs under the influence of this base revives the action of the heart, and the effects of the ptomaïne are not observed in atropinized animals.

Minute doses, administered hypodermically to rabbits, cause greatly increased salivary and lachrymal secretions, contraction of the pupils, profuse diarrhœa, ejaculation, voiding of urine, and death after convulsions of short duration.

Gadinine, $C_7H_{17}NO_2$ (not to be confounded with the brown substance from cod-liver oil, to which De Jongh gave the same name), is a base whose chloroplatinate crystallizes in golden-yellow scales, sparingly soluble in water, and whose chloride crystallizes in thick, colorless needles, soluble in water, but insoluble in alcohol. No chloraurate exists. Crystalline precipitates are formed with phosphotungstic, phosphomolybdic, and picric acids. It appears to be non-poisonous.

Bocklisch obtained from putrid fish cadaverine, putrescine, neuridine, methylamine, trimethylamine, and ethylamine. The most abundant and uniformly present were cadaverine, putrescine, and methylamine. In the first stages, cadaverine was detected without putrescine, which subsequently exceeded the former alkaloid in amount. Large quantities of trimethylamine, accompanied by methylamine, are formed in the putrefaction of herrings. Both of these bodies have been long known to exist in herring-pickle. The same pickle also contains choline, which yields trimethylamine on decomposition.

Methylamine is the predominating base produced by the putrefaction of pike.

None of the bases isolated by Bocklisch is actively poisonous, although the extracts from which they were separated had markedly toxic powers.

Ptomaïnes from Cheese.—From cream-cheese which had undergone complete putrefaction, Brieger obtained neuridine and trimethylamine.

Vaughan (*Zeitschr. f. Physiol. Chem.*, x., 146) obtained from cheese, which had caused symptoms of poisoning, a crystalline substance which caused, when placed upon the tongue, a sharp, burning sensation, dryness of the throat, a sense of discomfort, and diarrhœa. This substance, whose composition was not determined, although the unusually constructed name *tyrotoxicon* was given it, produces a blue color with ferric chloride and potassium ferricyanide, and reduces hydriodic acid ; but it does not react with the general reagents for the alkaloids. It is readily soluble in water, alcohol, and ether.

PTOMAÏNES FROM PUTRID GELATINE.—Nencki, in 1876, was the first to determine the composition of an animal alkaloid. To the product which he obtained he gave the name of *collidine*, $C_8H_{11}N$. This base was produced by the decomposition of a mixture of gelatine, ox-pancreas, and water, during five days at 40° C. The free base is an oily substance, of a peculiar but not disagreeable odor, which absorbs carbonic acid from the air, to form scale-like crystals of a carbonate. The chloroplatinate crystallizes in fine, flat needles. Nencki considered this base as being isophenylethylamine, $C_6H_5—CH\langle^{CH_3}_{NH_2}$

Brieger subjected a strong solution of glue to putrefaction for ten days at 35° C. and obtained considerable quantities of neuridine, some dimethylamine, and a small quantity of a substance having a physiological action similar to that of muscarine.

PTOMAÏNES FROM POISONOUS MUSSELS.—In 1885 a number of cases of serious poisoning occurred at Wilhelmshaven in consequence of eating mussels (*Mytilus edulis*) (see below). From the fresh mollusks (living at the outset of the process) Brieger obtained, besides other bases, a poisonous alkaloid, to whose action their toxic qualities are due: *Mytilotoxine*, $C_6H_{15}NO_2$. The free base has a disagreeable odor, which it loses rapidly on exposure to air, and at the same time it becomes non-poisonous. It is decomposed on being heated with caustic potassa. Its chloride crystallizes in tetrahedra and is intensely poisonous, causing the same symptoms as the mussels. The chloraurate crystallizes in microscopic cubes, which fuse at 182° C. With the customary general reagents only oily precipitates are produced.

The remaining bases are non-poisonous, and consist chiefly of *betaïne=oxyneurine*, $C_5H_{11}NO_2$.

The poisonous mussels, when allowed to putrefy sixteen days, contain no poisonous base, but yield cadaverine, putrescine, and notable quantities of trimethylamine.

ALKALOIDS PRODUCED IN THE NORMAL LIVING BODY.—In 1849, Liebig obtained *creatinine*, $C_4H_7N_3O$, from the urine of the dog, and the same body was subsequently obtained by Pettenkofer from normal human urine, by Sokoloff from the urine of the calf, and by Valenciennes and Frémy from the muscular tissue of crustaceans. The occurrence, in the situations named, of this substance, which is alkaline in reaction, caustic, and capable of neutralizing acids, and of displacing ammonia from the ammoniacal salts, proves that an alkaloid may be produced in the normal living body.

It would seem probable that the rapidly lethal secretion of the poison-glands of certain serpents owes its activity to the presence of an alkaloid, yet the researches of Gautier (*Bull. Acad. d. Méd. d. Paris*, 2 Sér., x., 947) with the poison of the cobra capello (*Naja tripudians*) indicate that, although the secretion contains two relatively non-poisonous alkaloids, the most actively poisonous constituent of the venom is not alkaloidal in character, although it contains nitrogen.

From the poisonous secretion of the salamander (*Salamandra maculata*), however, Zalesky ("Med. Chem. Unt.," i., 85) obtained an alkaloid capable of producing effects similar to those caused by the secretion itself—anxiety, trembling, epileptiform convulsions, opisthotonos, and death. This alkaloid, *salamandrine*, $C_{34}H_{60}N_2O_5$, is amorphous, soluble in water and in alcohol, and strongly alkaline.

Gautier ("Ptomaïnes et Leucomaïnes," Paris, 1886) describes several bases as having been obtained from fresh beef and from Liebig's meat-extract. For these and similar substances produced in the body during life he has suggested the name *leucomaïnes* (λεύκωμα = white of egg), as indicating their probable origin from the albuminoids.

Xanthocreatine, $C_5H_{10}N_4O$, crystallizes in thin, sulphur-yellow, micaceous plates, resembling those of cholesterine in form, and greasy to the touch. Its taste is faintly bitter and, in quantity, it gives off a faint cadaveric odor. It is very soluble in water, and soluble in hot, strong alcohol. Its reaction is amphoteric. It resembles creatinine in its properties. Potassium iodhydrargyrate and iodine in potassium iodide cause no precipitates in the solutions, but phosphomolybdic acid causes a grumous, yellow precipitate.

"Xanthocreatine is poisonous in moderate dose. It causes depression, somnolence, extreme fatigue, defecations, and repeated vomitings in animals."

Crusocreatinine, $C_5H_8N_4O$, is a crystalline substance of an orange-yellow color, feebly alkaline, and slightly bitter, whose chloride and chloroplatinate crystallize in easily soluble needles, and whose chloraurate forms difficultly soluble granules, which are decomposed by heat. It also resembles creatinine in its properties.

Amphicreatine, $C_9H_{19}N_7O_4$, crystallizes in brilliant, oblique prisms of a yellowish-white color. It is tasteless and faintly basic. It resembles creatine in its properties.

Pseudoxanthine, $C_4H_5N_5O$, is a sulphur-yellow, crystalline body, resembling xanthine in its chemical and physical properties.

Besides the above, Gautier mentions two unnamed substances, $C_{11}H_{24}H_{10}O_5$ and $C_{12}H_{25}N_{11}O_5$, as obtained from normal muscular tissue.

These bodies are closely related to each other, and to creatine and creatinine; and the influence of the addition or removal of the group CHN in their formation is of interest, particularly when considered in connection with the recent discovery of a polymere of hydrocyanic acid, the *adenine* of Kossel.

Adenine (ἀδήν = a gland), $C_5H_5N_5$, is a basic substance, although neutral in reaction, obtained by Kossel (*Zeitsch. f. Physiol. Chem.*, 1886, x., p. 250) from the pancreas of the ox, and as a product of decomposition of nucleïn. It crystallizes in long needles, easily soluble in hot but difficultly soluble in cold water, insoluble in ether, chloroform, and alcohol. It forms well-defined salts with mineral acids. By the action of potassium nitrite it is converted into hypoxanthine, $C_5H_4N_4O$. When heated with caustic potash to 200° C. a large quantity of potassium cyanide is produced.

Urinary Alkaloids.—Besides creatinine, whose presence in normal urine is unquestioned, other alkaloids have been supposed to exist in that liquid. It has further been claimed (Picard, Schöltin, Oppler, Chalret, *et al.*) that the symptoms of uræmic poisoning are due, not so much to the retention of urea, as to the retention of certain toxic alkaloidal bodies included in the so-called extractive matters of the urine.

While it may be considered as probable that the urine under pathological conditions may contain alkaloidal substances, and even possible that such bodies may be produced in minute quantity by the normal organism, from which it is separated by the urine, the evidence in favor of such views is as yet entirely physiological and unsupported by isolation and identification of any supposed alkaloid.

Charrin and Roger (*Comptes Rendus Soc. d. Biol.*, iii., 607, Paris, 1886), experimenting upon rabbits, found human urine to be less poisonous to those animals than their own. The former in doses of forty cubic centimetres, in intravenous injection, causes punctiform contraction of the pupil immediately, exorbitism and injection of the vessels of the ear, followed by a semicomatose condition, sometimes interrupted by slight convulsive movements, in which the animal dies. With fifteen cubic centimetres of rabbit's urine there is neither exorbitism nor dilatation of the auricular vessels, but there are extremely violent tetanic convulsions. Immediately after death the heart is found arrested.

The authors consider that seventy-five to eighty per cent. of the toxicity of urine so administered is due to the action of the potassium salts. While the potassium salts are unquestionably poisonous, and therefore may be justly credited with a considerable share in the toxic effects of urine, their action does not correspond closely with the symptoms described; and the differences between the action of urines of different animals would seem to indicate the existence in them of different poisons, whether they be or be not alkaloidal.

Peptic Alkaloids.—The actively poisonous effects pro-

duced by inoculation with recent cadaveric matter cannot be ascribed to any of the alkaloids above mentioned, as those which are produced during the earlier stages of putrefaction are either non-poisonous or only slightly toxic, the actively poisonous alkaloids being only produced at a later stage.

One of the earliest products of putrefaction is a substance seemingly identical with the peptone produced by the action of pepsin or trypsin upon albuminoids, and formed, probably, in cadaveric matter in a similar manner by false ferments, similar to those of the gastric and pancreatic secretions existing in the animal tissues. As it has been shown by numerous experiments (Schmidt-Mühlheim, Hoffmeister, Faus, *et al.*) that a solution of peptone, when injected into the circulation, causes violent symptoms of poisoning, the supposition that the poisonous qualities of recent cadaveric matter is due to peptone, or to some substance formed at the same time with peptone, is not strained.

Indeed, Brieger (*loc. cit.*, i., 14) has separated from peptone, produced by the action of pepsin from the pig upon fresh fibrin, a substance (or mixture of substances) whose composition was not determined, but which presents some of the characters of the alkaloids, and to which the name *peptotoxine* was given.

This substance, which is actively poisonous in minute doses, crystallizes with difficulty, passes from both acid and alkaline aqueous solutions into amylic alcohol, is insoluble in ether, benzol, and chloroform, and very soluble in water. It is quite stable, and is not decomposed by boiling, or by treatment with sulphuretted hydrogen or with caustic alkalies. Its solutions are neutral. With Millon's reagent it gives a white precipitate, which turns bright red on the application of heat. Its solutions form precipitates with phosphomolybdic acid, phosphotungstic acid, cadmium-potassium iodide, potassium iodhydrargyrate, cadmium-bismuth iodide, auric chloride, mercuric chloride, iodine in potassium iodide, and iodine in hydriodic acid. With potassium ferricyanide and ferric chloride it forms Prussian blue.

The same substance was obtained from Witte's peptone, and from putrefying fibrin, caseïn, brain, liver, and muscular tissues. If putrefaction has lasted eight days it is no longer obtainable.

PATHOGENIC PTOMAÏNES.—Spica, in 1880 (*Gaz. Chim.*, x., 492), seems to have been the first to have obtained a ptomaïne from a pathological product during life.

As albuminoid substances, under process of putrefaction after death, produce alkaloidal substances, some of which are non-poisonous, while others are actively toxic, it seemed probable at an early period of the history of the ptomaïnes that the same or similar substances might be produced during life, and that, if produced, they might be the causes of certain pathological manifestations.

The researches of Koch and his followers have brought to light a number of well-defined pathogenic bacteria, the method of whose action seemed to be the most readily accounted for on the hypothesis that alkaloids or other poisons are produced during the processes of nutrition of these minute organisms. This view was strengthened by the observation of Passet (*Fortschritte d. Medicin,* iii.), that eight varieties of bacteria, cultivated from pus, were capable of producing lactic fermentation in sterilized milk; as well as by that of Brieger, that the pneumococcus of Friedländer and Frobenius is capable of producing formic and acetic acids and alcohol from carbohydrates.

Within the past two years the labors of Nicati and Rietsch, Pouchet, Villiers, and Brieger, have resulted in the separation and identification of several poisonous alkaloids from nutrient material in which pathogenic bacteria had been cultivated, as well as from the tissues and dejections of patients suffering from cholera and other diseases.

Ptomaïne of Asiatic Cholera.—Villiers (*Journ. d. Pharm. et d. Chimie*, 1885, Sér. 5, xi., p. 257) isolated 0.02 gramme of the chloride of a well-defined alkaloid from the internal organs of two cholera-patients. This base as well as its salts gave the following reactions: Potassium iodhydrargyrate, white precipitate; iodine in potassium iodide, brown precipitate; bromine-water and picric acid, yellow precipitate; auric chloride, light-yellow precipitate; tannin and mercuric chloride, white precipitates from concentrated solutions; platinic chloride and potassium dichromate, nothing; ferric chloride and potassium ferricyanide gave a blue color only after a time; sulphuric acid, a faint violet color, which soon disappeared. A guinea-pig which received 0.006 gramme of the alkaloid was seized in forty-five minutes with violent trembling of the anterior extremities, soon extending to the posterior also, and then diminishing and disappearing. The animal refused food for four days, when it died suddenly.

Nicati and Rietsch (*Journ. d. Pharm. et d. Chimie*, 1885, Sér. 5, xii., p. 292) obtained a fluid alkaloid by the Stas method from cultures of the comma bacillus. This base is volatile at 100°, and produces the same physiological action as the cultures. They obtained an identical substance from the blood and liver, removed two hours after death, from the body of one who had died suddenly in the algid stage of cholera. The same authors (*loc. cit.*, p. 385), in repeating their experiments under varying conditions, found the poisonous alkaloid to be produced in greatest amount at 35° after about ten days.

Pouchet (*Comptes Rendus*, c., 220–222; ci., 510, 511) isolated from the watery and almost colorless fæces of a cholera-patient an oily alkaloid, soluble in chloroform, possessed of the odor of the pyridine bases. It responds to the general reagents for alkaloids, and energetically reduces potassium ferricyanide, auric chloride, and platinic chloride. Its chloride is easily dissociated by heat or *in vacuo*. It produces actively poisonous effects, even when its vapor is inhaled. Traces of the same substance were found in the nutrient material of Koch's microbes.

Ptomaïne of Typhus.—Brieger ("Ptomaïne," ii., 68; iii., 85) obtained a base from cultures of the Koch-Eberth typhus bacillus in meat at a temperature of 37.5° to 38° C. for eight to fourteen days. This alkaloid has the composition $C_7H_{17}NO_2$, and has been named *typhotoxine*. The chloride is hygroscopic, forms an easily soluble chloroplatinate, crystallizing in needles; also a difficultly soluble chloraurate, crystallizing in prisms, which fuse at 176° C., and a difficultly soluble picrate. With reagents it behaves as follows: Phosphomolybdic acid, yellow, crystalline precipitate; phosphotungstic acid, white, crystalline precipitate; potassium-cadmium iodide, potassium iodhydrargyrate, iodine in potassium iodide, iodine in hydriodic acid, oily, non-crystalline precipitates; bismuth-potassium iodide, resinous precipitate. With Ehrlich's reagent (sulphodiazobenzol) it gives an immediate yellow color, which disappears on addition of a base. In cultures from which no typhotoxine is obtained there is much creatine or creatinine, while in those giving the best yield of the alkaloid the normal constituent of the meat is present in less amount. In bouillon, to which three per cent. of glycogen is added, the bacilli grow luxuriantly, without any decomposition of the glycogen.

This alkaloid causes a moderate increase in the flow of saliva and an acceleration of respiration. Later the animals lose control of the muscles of the extremities, without suffering true paralysis; they fall upon the side, and, if placed upon their feet, fall back helpless after a few steps forward. The pupils gradually dilate widely and become insensible. Convulsions do not occur. The frequency of the heart's action and the respiration gradually diminish. During the entire poisoning there is copious diarrhœa. After death the heart is always found contracted in systole, the lungs are highly hyperæmic, the other organs pale. The intestines are always strongly contracted, and their walls pale.

Ptomaïnes of Tetanus.—Brieger ("Ptomaïne," iii., 89; "Ber. d. Deutsch. Chem. Gesell.," xix., p. 3119) experimented with cultures of an anaërobe bacillus found by Nicolaier in earth-samples and capable of producing symptoms of traumatic tetanus in animals, and with cult-

ures of the same bacillus bred by Rosenbach from the wound of a man who died of tetanus. Two alkaloids endowed with similar physiological action were obtained.

One of these bases, *tetanine*, $C_{13}H_{30}N_2O_4$, is produced along with much ammonia. It forms a very soluble chloroplatinate, which crystallizes from alcohol in beautiful, light-yellow plates. The chloride is deliquescent and forms an easily soluble, crystalline compound with phosphomolybdic acid. With bismuth-potassium iodide it forms an amorphous precipitate, which soon becomes crystalline. The free base is a yellow, strongly alkaline syrup, which gives no blue color with ferric chloride and potassium ferricyanide.

The free base or its chloride, injected into mice or guinea-pigs, soon causes clonic or tonic convulsions of the greatest intensity, which terminate in death. The course of the poisoning is divisible into two stages. In the first the animal is depressed and lethargic, then it becomes suddenly uneasy and the diaphragm contracts energetically. The second stage is marked by convulsions, usually tonic, but occasionally clonic. Death occurs frequently in a violent convulsion. Frogs withstand the poison relatively better than warm-blooded animals, but when they succumb they become perfectly rigid in a position of pronounced opisthotonos. Guinea-pigs, when thoroughly under the influence of the alkaloid, exhibit very clearly the characteristic spasms of tetanus in the human subject and marked opisthotonos.

The other tetanizing ptomaïne has the composition $C_6H_{11}N$, and is a volatile substance, boiling at 100° C. In relatively large doses it produces in animals fibrillar contractions of diverse groups of muscles, particularly those of the neck and face. Motion is more and more interfered with until paralysis is established. Convulsions increase in intensity, attacking groups of muscles very violently. The animal lies with head thrown back and extremities extended, and, when pressed upon, makes movements as in swimming. Finally the animal falls upon its side and dies in a violent convulsion.

Chemico-Legal Considerations.—As the ptomaïnes, both those produced during putrefaction and those occurring as the products of pathogenic bacteria (the *toxines* of Brieger), as well as the so-called leucomaïnes, are true alkaloids, and as such are members of the same chemical group (function) as the vegetable alkaloids, the possibility that one of the former may be mistaken for one of the latter in a chemico-legal examination of a cadaver is obvious.

That such errors have actually occurred there can be no doubt. Three such cases are classical, and intimately connected with the history of the ptomaïnes. In the case of General Gibbone, who died in Rome under circumstances which awakened a suspicion of poisoning, two chemists who analyzed portions of the body were led to believe that death had been caused by *delphinine*. Upon a more careful examination, Selmi showed that the alkaloid obtained from the body of the deceased did not respond to several of the reactions of delphinine, and that it was not that alkaloid, but a ptomaïne ; which was also shown, by Ciaccia and Vella, to differ from delphinine in that it caused arrest of the heart in systole, whereas in poisoning by the vegetable alkaloid the heart is arrested in diastole.

In the case of the widow Sonzogno, who died in Cremona in 1873, the body was exhumed twelve days after death, and the experts who made the analysis testified upon the first trial, at Brescia, to having detected the presence of morphine, while three other experts considered it probable that the substance isolated was a ptomaïne. Selmi, to whom the matter was referred, showed conclusively, by an examination of the chemical and physiological properties of the isolated alkaloid, that it was not morphine, but a ptomaïne.

In the Brandes-Krebs case, tried in Brunswick in 1874, the two chemists who made the analysis claimed to have detected, besides arsenic, coniïne. Otto, in a revision of the work, showed that the substance considered as coniïne, although very similar to that alkaloid and to nicotine, could not be identical with either alkaloid or with any other known vegetable base.

The occurrence of mistakes like those mentioned, and the possibility of their recurrence, for a time cast doubts on the reliability of the tests for the vegetable alkaloids, and even formed an apparent foundation for the claim, on the part of defending counsel in cases of trial for alkaloidal poisoning, that all analytical results in such cases are unreliable and illusory.

Although this extreme view is not well founded, the existence of the ptomaïnes renders the work of the toxicologist most difficult in cases of alkaloidal poisoning, particularly if the alkaloid used be one of infrequent occurrence, and makes it incumbent upon him to exercise the greatest caution and deliberation before reaching a conclusion, which can only be arrived at with certainty after an exhaustive analysis with every known test.

Attempts have been made to devise some test or tests by which the ptomaïnes as a class might be differentiated from the vegetable alkaloids. No such reagent has been found, nor will it be. The ptomaïnes are as distinctly alkaloidal in their nature as the vegetable alkaloids, and are therefore possessed of all the characterizing properties of the group, and, consequently, any quality or reaction common to all ptomaïnes will be found to be possessed by the vegetable alkaloids as well. No reagent is known by which vegetable acids can be distinguished from those of animal origin, although such acids were among the earliest known organic compounds.

The principal reagents by which it has been claimed that the ptomaïnes might be distinguished from vegetable alkaloids are those of Brouardel and Boutmy,* and of Trotarelli.

The reaction of Brouardel and Boutmy consists in the formation of a blue color with ferric chloride and potassium ferricyanide, which, it was claimed, was brought about by the ptomaïnes, and not by the vegetable alkaloids. This reaction, due to the reduction of the ferricyanide to ferrocyanide and the formation of Prussian blue, is based upon the facility with which the ptomaïnes are oxidized and their consequent reducing action. There exist, however, ptomaïnes (see tetanine, *supra*) containing oxygen which fail to respond. On the other hand, any substance endowed with reducing powers exhibits the reaction, and among such substances are the vegetable alkaloids morphine, apomorphine, muscarine, aconitine, eserine, liquid hyoscyamine, amorphous ergotinine, atropine, and strychnine.

The reaction of Trotarelli consists in the addition of sodium nitroprusside and then paladium nitrate to the material under examination. With the ptomaïnes a play of colors is observed. The reaction is no more reliable to differentiate the ptomaïnes from the vegetable alkaloids than that of Brouardel and Boutmy.

Notwithstanding the failure of such reactions, it is possible to clearly establish the presence or absence of vegetable alkaloids without possibility of error due to the presence of ptomaïnes. No single reaction can be relied upon, even with alkaloids giving such marked reactions as strychnine and morphine. In cases of suspected poisoning the identity of the alkaloid should be established by *all* of its characters, chemical, physical, and physiological. Before applying the tests or determining the physiological and physical properties of the alkaloid under examination, it should be separated in a condition as nearly approaching purity as possible.

Many vegetable alkaloids resemble a corresponding ptomaïne in one or more of its characters, but a difference is found in others which will enable the two to be distinguished. Thus Wolkenhaar (*Correspondenzbl. d. Ver. Anal. Chem.*, i., 33, 37) describes a ptomaïne which resembles nicotine in that it is a yellowish liquid, turns brown in air, is completely volatile, and has the same odor, not disappearing on addition of oxalic acid, as nicotine, but differing from the alkaloid of tobacco in forming a non-crystallizable chloride and in failing to give Roussin's reaction with iodine in ethereal solution. In a case tried in Verona, Ciotto mistook for strychnine

* The reaction was first observed by Selmi, but was not considered by him as characteristic of ptomaïnes.

a ptomaïne which gave crystals with iodine in hydriodic acid, was reddened by hydriodic acid, and gave with potassium dichromate and sulphuric acid a yellow precipitate and a blue or violet color, although it was not bitter and had no tetanizing action. Brouardel and Boutmy (*Arch. d. Ph.*, Bd. 219, p. 462) met with a ptomaïne in a cadaver that had laid in water eighteen months, which closely resembled veratrine in that it was colored violet when warmed with sulphuric acid, brick-red with sulphuric acid and barium peroxide, and cherry-red when warmed with hydrochloric acid. It was distinguished from veratrine by the immediate reduction of ferricyanide and the absence of the characteristic muscular spasms caused by the vegetable alkaloid.

So far as known, no ptomaïne has been obtained which corresponds in *all* its characters with an alkaloid of vegetable origin, with the exception of muscarine. In a case of poisoning by that alkaloid its detection in the body after death could only serve as evidence confirmatory of that derived from an observation of the symptoms of muscarine-poisoning observed during life.

Sausage-Poisoning (*Allantiasis*, *Botulism*).—In the latter part of the last and the beginning of the present century there occurred in Würtemberg and the other states of Southwestern Germany numerous cases of serious and fatal poisoning, which were traceable to the ingestion of the different varieties of sausage which there form a staple article of diet. According to Buchner and Kerner, the first published record of a case of botulism is in the "Acta phys. med. Colleg. Med. Onoldini," 1735. Schlossberger estimates that, up to 1853, about four hundred such cases had occurred in the district mentioned, of which one hundred and fifty had terminated fatally.

Although it is certain that many, if not the great majority, of the older cases were not due to a poison, but to the then unrecognized trichina spiralis, well-defined cases of true botulism, with entire absence of trichinæ in either the sausages or the muscular tissue of the victim, have occurred in recent years, not only in Germany, but also in France, England, and the United States.

The poisonous sausages are always liver- or blood-sausages, or others of large size, smoked, and more or less softened in the interior. The central portion is in some cases of a grayish tinge, pulpy, and has a rancid or sharp and somewhat acid taste. The cortical portion is sometimes inert, while the central portion is actively poisonous. The odor is sometimes musty, but in most cases in no way peculiar. The odor of putrefaction is not observed.

It is highly probable that the poisonous character of such sausages is due to the formation in them of a ptomaïne, although efforts to isolate the alkaloid have not proved successful. Schlossberger obtained from poisonous sausages an ammonia having a nauseous odor, which he could not obtain from fresh ones (Maschka, *Handbuch d. Ger. M.*, ii., 514); and Ehrenberg obtained choline, neuridine, dimethylamine, and trimethylamine from a similar source (*Zeitschr. f. Physiol. Chem.*, xi., 239). None of these substances is, however, capable of causing symptoms resembling those of botulism, or possessed of sufficiently active poisonous qualities to account for the violent effects of the sausage-poison.

The action of the poison is usually manifested in from twelve to twenty-one hours after it has been taken, although Eichenberg (*Diss.*, *Göttingen*, 1880) mentions a case in which two to three hours elapsed, and Kaatzer (*Deutsch. Med. Wochenschr.*, 1881, vii.,) cites two cases in which the poisonous effects began in one hour. The recorded cases with a longer interval than twenty-four hours are probably cases of parasitic disease.

The total duration of the poisoning is very variable, as shown by the 48 cases cited by Müller (*Deutsche Klinik*, 1869, 1870), of which 6 died upon the first day, 19 from the second to the seventh day, 16 from the eighth to the tenth day, 4 from the eleventh to the twenty-first day, and 3 after long illness. Recovery is usually slow, and may require several months.

The earliest symptoms are usually gastric—nausea, abdominal pain, not intense, but increased on pressure; vomiting of yellow, pulpy, sour, or bitter masses, and, not infrequently, purging. These symptoms, which in light cases are sometimes the only ones observed, are never so intense as in cholera-morbus, and are never accompanied by the cyanosis and cramps which occur in poisoning by mussels, by certain varieties of fish, and by cheese.

Following upon the gastric symptoms, either immediately or after an interval of a day or more, or, in some cases, without the occurrence of gastric symptoms, the true poisonous action is established. The secretions are much diminished or arrested, the mouth, tongue, and pharynx are dry, and neither saliva, perspiration, nor tears are secreted. The skin is wrinkled and cool. The tongue is covered with a whitish coat, the buccal mucous membrane is marked with aphthous patches, and the pharynx is inflamed or ulcerated and coated with a grayish-white deposit. The voice is hoarse, and in some cases there is a dry cough. The urine seems to be the only secretion which is not diminished. The nerve-supply of the eye and ocular muscles is markedly interfered with. There is diminished vision, which may reach the point of temporary blindness; objects appear colored and sometimes double, and the field of vision is traversed by sparks. The muscles moving the globe are partially paralyzed and the pupil dilated. Paralysis of the levator palpebræ superioris, with consequent ptosis, is characteristic. Interference with deglutition is a marked and constant symptom, and is frequently accompanied by interference with the movements of the tongue and with hoarseness, or even aphonia.

Apart from the above symptoms, referable to paralysis of individual cranial nerves, the cerebral functions and those of the spinal nerves are but little interfered with. Consciousness is perfect, almost up to the time of death. The functions of the sensory nerves remain unimpaired. There is great and progressive muscular weakness, which is probably due rather to the same cause as the progressive emaciation which also occurs—*i.e.*, interference with nutrition by dysphagia or aphagia—than to any action upon the motor spinal nerves. The patient complains chiefly of the derangements of vision and of attacks of suffocation.

Death is caused in many cases by marasmus. In some cases suffocation, with or without preceding convulsions, is the cause of death; or sometimes suffocation due to entrance of particles of food into the air-passages.

The symptoms of botulism present some similarities to the action of certain poisons. The solanaceæ—belladonna, stramonium, and hyoscyamus, and the alkaloids obtained from them—produce not only dilatation of the pupil and paralysis of accommodation, but also marked dysphagia and diminution of the secretions. But they also produce cerebral symptoms—delirium and hallucinations—which are absent in botulism. Moreover, the pulse is much more rapid in poisoning by the solanaceæ than in botulism, and the course of the poisoning occupies much less time.

The similarity between botulism and poisoning by gelseminum or its alkaloid is still closer. The effects upon the eye and its muscles, including ptosis, are the same in the two forms of poisoning, which may, however, be readily distinguished by the much more rapid and, in cases of recovery, temporary action of the vegetable product.

In trichinosis the mydriasis and paralysis of accommodation which occur in botulism are of very rare occurrence, while the cerebral symptoms and sopor which are observed in the former do not occur in the latter. A positive diagnosis may be made after death, or even during life, by microscopic examination of the muscular tissue.

No characteristic post-mortem appearances are recognizable. The body is emaciated, and the skin bleached and parchment-like. Rigor mortis begins early and continues longer than usual, and putrefaction is delayed in some cases, but very rapid in others. The mucous membrane of the mouth and pharynx is often white, dry, and parchment-like, or horny. The gastric mucous

membrane is frequently injected and sometimes ecchymotic. The spleen is sometimes enlarged, congested, and extremely soft and friable. The blood, as a rule, is dark, and contains no foreign organisms or elements. The corpuscles are unaltered. The lungs are frequently congested and œdematous.

POISONOUS FISH.—Not only do fish become poisonous when putrid, but certain species are either always poisonous to the human subject or become so at times. In some cases the same fish, eaten with impunity by one person, proves actively poisonous to another.

Poisonous fish are usually the inhabitants of warm climates. Stuart Eldridge (*Med. Times and Gaz.*, 1879, ii., 377) mentions a Japanese fish, a species of Tetrodon, called by the natives *fugu*, whose use as food is interdicted by law. In three cases of poisoning by this fish, one of which terminated in death, the symptoms began in from fifteen to forty-five minutes. There were headache, nausea, great muscular weakness, failure of the pulse and respiration, diminution of temperature, and total insensibility.

James Edwards (*Brit. M. Journ.*, 1884, i., 10) records a case of poisoning in a man, aged sixty-eight, by the flesh of the ray. In fifteen minutes the face began to swell; there was a burning sensation in the hands and back of the head; the feet were cold; the tongue swelled until it filled the cavity of the mouth, causing a choking sensation at the root of the tongue; the eyes were swollen and protruded. The patient suffered no pain but great dyspnœa and thirst and an intense itching of the skin. Consciousness was perfect. The patient vomited freely and soon recovered.

The roe appears to be the most actively poisonous portion of the fish. Belin (*France Méd.*, ii., 1458, Paris, 1886) reports the poisoning of a man of thirty, caused by eating three roed herrings broiled; the symptoms being chiefly gastric, and very violent and persistent. The same author refers to cases reported by Goertz, in which three members of a family who ate fresh roed fish suffered violent symptoms, while the other members of the family who ate milt fish were not affected. Similar cases are reported by Münchmeir (*Berl. Klin. Wochschr.*, 1875, xii., 4) and Naunyn (*Schmidt's Jahrb.*, 1884, 113).

Remy (*Comptes Rendus Soc. Biol.*, 7 Sér., iv., 14, 263, Paris, 1883) also concludes that the ovaries are the seat of the poison in poisonous fish.

It seems probable that fish-poisonings are due to the formation, either normally or in a diseased condition of the animal, of alkaloidal substances similar to that obtained by Brieger from poisonous mussels (see above), although no such substance has as yet been isolated.

POISONOUS MUSSELS.—The edible mussel (*Mytilus edulis*) frequently becomes actively poisonous, probably by reason of changes in the character of the surrounding water A case is recorded (*Guy's Hosp. Rep.*, 1850, 213) in which serious symptoms and a scarlatinal eruption were caused by eating two mussels, and another (*Med. Times and Gaz.*, 1864, 496) in which similar effects followed the ingestion of a single mussel. Death has resulted in several instances (*Med. Times and Gaz.*, July 28, 1860; *Lancet*, 1873, i., pp. 247, 323; "Fodéré Méd. Lég.," iv., 85).

Farrar (*Brit. Med. Journ.*, 1882, i., 939) reports the case of a strong, temperate, well-built man of sixty who had been in the habit of eating mussels without ill effects. Immediately after eating about twenty, without removing the "moss," or byssus, he felt sick and had griping abdominal pain. In half an hour he vomited and purged severely five or six times. In two and a half hours he was in a state of extreme collapse. The hands and feet were cold; the radial pulse was almost imperceptible and much increased in frequency. The face was pale, except occasional hectic flushes on the cheeks, the nose white, pinched, and quite bloodless, the pupils normal, the tongue clean. There was loud wheezing and rattling respiration, with frequent yawning and sighing. The patient fainted frequently, in spite of large doses of brandy. There were repeated clonic spasms, apparently implicating all the muscles of the body. He was perfectly calm and conscious, suffering no pain but great thirst and itching over the entire surface. There was neither sense of constriction of the throat nor headache. Surrounding objects appeared misty. The chest was covered with a rash resembling erythema. The next morning recovery was complete.

It was found by Max Wolff (*Arch. f. Path. Anat.*, civ., 108, 202) that the mussels which caused the poisonings at Wilhelmshaven, in 1885, came from a basin containing stagnant water, which was also the habitat of a poisonous star-fish (*Asterias rubeus*); but that the mussels from the neighborhood of the sluices, where the water was changed, were not poisonous. Schmidtman and Virchow (*Arch. f. Path. Anat.*, civ., 161, 179) found that the poisonous mussels, when transplanted to pure sea-water, lost their poisonous qualities completely in from two to four weeks; while non-poisonous mussels became actively toxic after two to three weeks' sojourn in the stagnant water of the basin. The poisonous individuals have a somewhat lighter and more striped shell than such as are innocuous. As mentioned above, Brieger obtained a poisonous alkaloid from the poisonous mussels.

POISONOUS CHEESE, MILK, BREAD.—It occasionally happens that a single cheese, produced along with many others at a properly conducted factory, causes symptoms of violent, irritant poisoning in all who partake of it, without presenting any peculiarity of appearance, odor, or taste which would indicate its poisonous qualities to the human senses, although dogs and cats are able to distinguish the poisonous cheese from a sound one, apparently by the sense of smell.

In cheese-poisoning the symptoms are chiefly those of irritant poisoning—severe vomiting and purging, dizziness, and great prostration, beginning in from one to four hours. The pulse is feeble and irregular, and the face is markedly cyanosed. Although the symptoms are frequently very severe, no fatal case is recorded.

The poisonous constituent of such cheeses, the so-called tyrotoxicon of Vaughan (*vide supra*), may either be produced by incipient putrefactive changes in the cheese or may pre-exist in the milk of which it has been made.

Milk has been known to produce serious outbreaks of poisoning or disease. In many of these the injurious effects are to be attributed, not to the presence of any putrid alkaloid in the milk, but to adulteration with impure water. Thus, in an outbreak which occurred in Aberdeen, in April, 1881, and in which three hundred and twenty-two persons were affected and three died, the milk as taken from the cows was found to be perfectly good, while the water used in the dairy was dangerously contaminated with the same material as that found in the contaminated milk (Beveridge).

Moreover, the recent researches of Power and Klein, concerning an outbreak of scarlet fever in London, seem to show that the disease may be caused in the human subject by the use of milk obtained from cows suffering from a similar disorder.

But apart from such instance of disease-transferral, cases have occurred in which true poisoning has been caused by milk. Firth (*Lancet*, 1887, i., 213) describes the cases of ten soldiers confined in a military prison. Of these, one who took none of the milk in question was not affected. The other nine were seized with nausea, vomiting, dryness of the fauces, a sense of constriction of the throat, colic, purging, and a tendency to collapse in some, in others a tendency to stupor. All recovered. The milk was apparently of good quality. A portion was coagulated, filtered, rendered feebly alkaline with caustic potash, and agitated with ether. The ether on evaporation left a semi crystalline, moist residue, having a mawkish, sickly odor and a strongly pungent taste. This substance caused nausea, dryness of the fauces, and headache in the human subject, and purging and vomiting in a dog. Attempts to produce the same substance from milk kept at 80° F. were only successful after three months. Firth suggests the name *lactotoxine* for this substance. Is it identical with tyrotoxicon?

Cases of poisoning by articles of food into whose composition milk enters are of occasional occurrence. An interesting instance of this form of poisoning, indicating the influence of different degrees of heat upon the toxic substance, is reported by Allen (*Med. Times and Gaz.*, 1878, ii., 519; *Sanit. Rec.*, London, 1878, ix., 257). Two bread-puddings were made of bread-scraps, milk, eggs, sugar, nutmeg, and currants. One was baked in a quick oven and caused no untoward results; the other was baked in a slow oven and caused severe poisoning in all who partook of it, and two deaths. The symptoms were those of violent, irritant poisoning, with severe vomiting and purging, greatly accelerated pulse, and rapid unconsciousness. The pudding which caused the poisoning was fed to a six-weeks-old puppy and to mice without the production of any toxic effects. It was not bitter in taste, did not exhibit the reactions of ergotine, gave off an unmistakable odor of herrings (methylamine) with caustic soda, and the alkaline solution assumed a brilliant lake-red color on standing. When a slice of bread was soaked in milk and sugar, and a portion of the poisonous pudding placed at one end, the substance giving the above reaction was gradually produced throughout the bread.

R. A. Witthaus.

PUBERTY (Lat. *Pubertas*, from *pubeo*, *pubere*, to become mature, or fit for procreation). By this term is meant that period of life when the human being becomes fitted for reproduction, evidence of which is afforded by rapid development of the sexual organs; for hitherto these organs had grown little from the period of infancy, and no exercise of their function was possible. Besides, it is usual for accelerated growth of the whole body to take place at the same time, and in the male the voice undergoes change, becoming an octave lower in pitch, from enlargement of the vocal organs. During the progress of this change the voice is unsettled, and often varies in a single utterance from one to the other key. In both sexes the pubic region becomes clothed with a hairy growth, followed later by the same growth in the axillæ, and, in the male, by the beard. In the female, particularly, there is a rapid deposit of fat in the subcutaneous cellular tissue of the breast and extremities, producing that roundness of form which contributes so much to the accepted type of beauty, and the deficiency of which is so often supplied by art.

Along with these physical traits a marked change in *morale* takes place. The individual manifests instinctive consciousness of sexual maturity by newly awakened sensibilities toward individuals of the opposite sex, commonly of attraction, but sometimes of repulsion, or, rather, timidity and shyness. In the female, particularly, an air of decorum and dignity is assumed by those of well-balanced minds; while the ill-balanced become pert and forward. Boys, rather than girls, are apt to develop a lasting shyness of the opposite sex, greatly to their discomfort and disadvantage.

From this time in the male the testes, prostate, and Cowper's glands constantly produce their characteristic secretions, unless interrupted by special lesions, or by serious general disease. In the female the ovaries begin their regular function of discharging perfected ova into the uterus, repeated generally at intervals of four weeks, and attended with a sanguineous flux from this organ, which lasts normally for three or four days. This function of menstruation, except when suspended by pregnancy and lactation, should recur regularly throughout the reproductive life of woman, which usually embraces a period of from thirty to thirty-five years. The developed mammæ become capable of assuming their function, whenever called for by the wants of offspring.

In the female the condition of puberty is preceded, for a varying time and in a varying degree, by certain disturbances, due to the new determination of blood to the sexual organs. Among these, headache, backache, corporeal and mental lassitude, palpitation, hæmorrhage from the nose, the lungs, and the stomach, are most frequent, and such nervous deviations as result frequently in hysteria and sometimes temporary insanity. At this period in both sexes nutrition is at its highest activity, and hæmorrhages are remarkably well tolerated. An inherited proclivity to disease, particularly pulmonary consumption, is apt at this time to manifest itself.

The access of puberty commonly occurs at the age of from fourteen to sixteen years in the male, and a year earlier in the female, for the temperate regions of the world. Considerable variation is found, however, beyond these limits in both males and females. The researches of Thomas More Madden, in the British Isles, have resulted in the following table of 497 cases, quoted from Quain's "Dictionary of Medicine:"

Under	twelve	years	4	menstruated	for the first time.
At	"	"	17	"	" " " "
"	thirteen	"	50	"	" " " "
"	fourteen	"	94	"	" " " "
"	fifteen	"	138	"	" " " "
"	sixteen	"	105	"	" " " "
"	seventeen	"	65	"	" " " "
"	eighteen	"	10	"	" " " "
Over	"	"	14	"	" " " "

Puberty is generally admitted by good authorities to occur somewhat earlier in hot climates, and the prevalence of very early marriages in tropical regions has incorrectly led to an impression of correspondingly early puberty. Undoubtedly habits of idleness and luxury hasten it, as a life of severe labor, hardship, and privation tends to retard it. Late appearance of puberty sometimes results from ill-health, and is not the cause thereof, as is supposed by the laity. In such cases it is sufficient to treat the actual disease or condition. Whenever retarded menstruation coexists with good general health, with or without other signs of delayed puberty, no medical interference is called for.

Instances of abnormally early puberty are on record, and are quite compatible with good general health. In vol. xli. of the "Medico-Chirurgical Transactions" is a table of 13 cases reported by various medical writers, which is here presented:

Title of work.	Author's name.	Sex.		Age when menses appeared.
		M.	F.	
Philosoph. Trans., 1754, vol. xliii	Dr. Mead	1	.	....
Med.-Chir. Trans., vol. i	Mr. Anthony White	1	..	....
" " " " ii	Mr. Cooke	..	1	Never menstruated.
" " " " ii	Dr. Martin Wall	..	1	9 months.
" " " " iv	Sir Astley Cooper	..	1	3 years.
" " " " xi	Dr. G. Breschet	1		....
" " " " xii	Mr. South	1	..	....
Med. and Phys. Jour., vol. xxv	Dr. Cookson	..	1	3½ years.
Midland Med. Reporter, vol. i	Dr. Burne	1	..	....
Med. Gazette, 1832	Dr. Ledsean	..	1	3 years.
" " 1840	Dr. Peacock	..	1	Nearly 5 yrs.
North. Jour. Med., 1845; Taylor's Med. Jurispr.	Mr. Whitmore	..	1	A few days of age.
Lancet, 1848	Mr. Embling	..	1	2 years.

In the first of the above list the external signs of puberty (enlargement of the sexual organs) occurred at the age of twelve months. This child died in 1752, at the age of five years, of pulmonary consumption, having an appearance of premature senility.

The third case had the usual appearances of precocious maturity, except size, physiognomy, and intelligence. The mammæ began to enlarge at the age of eighteen months.

The fifth case, at four and one-half years, had the breasts as well developed as a woman of twenty years, and was very broad in the chest and loins. At six years she was 4 feet 1 inch in height, menstruated every three weeks, and had hair in the axillæ. A sister, then aged seventeen, had not yet menstruated.

The sixth case, at three years of age, was 3 feet 6¼ inches in height, and weighed 50 pounds; had enlarged generative organs, with frequent erections and seminal stains on his linen. The voice had changed in pitch.

The seventh case was unusually large at birth, with hair as long and abundant as is usually found at five

months, prominent pudenda, and a hoarse voice. At four months hair appeared on the pubes, the penis and testes began to enlarge, and at fifteen months the glans was entirely exposed. Seminal stains appeared soon after. At the age of three years and four months he was 3 feet 7 inches in height, and weighed 64 pounds. Length of penis, flaccid, 3 inches; erect, 6 inches.

Another case, not included in the above table, born in 1806, showed at twelve months of age a change of voice, enlargement of generative organs, and hair on the pubes. At three years he appeared physically mature, though without a beard. Height, 3 feet 4½ inches; weight, 51½ pounds; circumference of cranium, 20 inches; of waist, 24 inches.

The extreme sexual and general physical precocity of these cases was not attended with corresponding intellectual development, and the condition, as a whole, must be regarded as an unfortunate one.

Inasmuch as the period of puberty, especially with girls, is attended by an important change in the direction of the nutritive energies, and sometimes with alarming disturbances of the nervous functions, it is clear that the requirements of physical, and still more of mental, exertion should be carefully regulated. This has particular reference to school duties, which are apt to be unduly imposed by teachers, encouraged or prompted by the ambition of doting parents to witness and boast of scholastic attainments. The result is liable to be wreck of the nervous system, or prolonged nervous and muscular prostration.

The family physician is occasionally asked to relieve the painful or emotional phenomena of incipient puberty, or more frequently to bring on the menstrual flow. There is too great disposition on the part of mothers to request active medication. Sometimes it is required, but often a placebo is preferable. For headache the alkaline bromides are suitable, when there is evidence of determination of blood to the brain. Hysteria may call for valerian, asafœtida, or emetics. Persistent pain in the back would justify warm hip-baths, or even aloetic purging. In case of anæmia, quinine and iron would be indicated.

S. S. Herrick.

PUERPERAL CONDITION. The term puerperal, derived from two Latin words, *puer*, a child, and *parere*, to bear, strictly speaking, pertains to the condition or state of child bearing; but usage has restricted its application to that period succeeding parturition which commences with the completion of labor, and continues until the genital organs shall have recovered their normal condition. This restoration is usually accomplished in about six weeks, provided the processes of repair and involution are not interrupted by any complication, accident, or failure.

Certain constructive changes in the genital apparatus, incident to gestation and parturition, after fulfilling their several missions, must undergo destructive metamorphoses; traumatic lesions need to be healed; and the function of lactation is to be established or called into renewed activity.

Familiarity with the physiology of the puerperal state is essential, in order that any deviation from the line of normal progress may be promptly detected, and that dreaded pathological developments may be clearly recognized, intelligently combated, and, if possible, successfully resisted.

SHOCK.—Immediately succeeding labor, the woman experiences a sense of fatigue and more or less shock, sometimes verging upon exhaustion. The fatigue and shock are generally most marked after severe and protracted labors, and in very susceptible subjects.

Rest, and occasionally an opiate, is the appropriate treatment.

CHILL.—The so-called post-partum chill occurs in some cases. It follows closely the expulsion of the child, and usually lasts several minutes. It possesses no pathological significance. It is probably due to the sudden cessation of the violent muscular effort associated with the severe expulsive pains, during which the surface of the body is profusely bathed with perspiration and the superficial vessels are filled with blood. The sudden withdrawal of the pressure of the gravid uterus and the consequent determination of the blood to the abdominal veins, producing a temporary depletion of the cutaneous capillaries, has been suggested as a possible cause.

No treatment is required beyond an increased amount of covering. The sensation and shivering soon subside, and are not followed by appreciable reaction. The occurrence of the chill may, very properly, be anticipated by supplying additional covering to the patient immediately after the extrusion of the child.

AFTER-PAINS.—The more or less rhythmical contractions of the uterus which occur, notably in multiparous women, for a few hours after delivery, frequently give rise to pains, similar, but by no means so severe as those experienced during labor. These pains are called after-pains, and are present in inverse ratio to tonic uterine contraction. Incomplete contraction allows intrauterine hæmorrhage, and the resulting clots provoke expulsive efforts on the part of the uterus, which may be the cause of very acute pains. Pains may likewise be caused without hæmorrhage by the contractions which follow frequently recurring relaxation. The reflex influence produced by the application of the child to the breast may also cause these pains. The existence of this sympathetic relation is sometimes happily utilized to secure firm and continuous contraction. After-pains are rarely observed in primiparæ. They are seldom protracted beyond twenty-four to forty-eight hours.

The proper treatment consists in securing and maintaining tonic contraction of the uterus. External pressure and manipulation, and ergot, usually suffice to accomplish this result. Opiates may, in addition, occasionally be required, and Dr. Barker[1] recommends full doses of quinine and the application of stimulating liniments to the hypogastrium in certain obstinate forms, which he regards as neuralgic in character.

TEMPERATURE.—Before the termination of labor the temperature is increased one or two degrees above the normal standard. After a day or two it recedes to, or even below, the level of health, though transient elevations of temperature, are liable to occur throughout the puerperal period. The continued increase of more than two degrees, especially if it be accompanied by a rapid pulse, denotes some complication, and is a sufficient cause for anxiety.

Lusk[2] considers a rise of from a half to one degree for the first six days, with slight evening exacerbations, as normal, and he confirms the opinion of Schroeder, that a temperature of 100.5° F. belongs within physiological limits and, moreover, that a rise even above this is not incompatible with a generally satisfactory condition of the patient.

Barnes,[3] on the other hand, positively affirms that no important increase of temperature is observed in puerperal women under healthy individual and sanitary conditions. He repudiates the observations made in lying-in hospitals, which show a rise of over 0.5° F., and declares this cannot be accepted as normal.

A slight fall of temperature, sometimes noticed within twenty-four hours after labor, is soon followed by a return to the standard. The increased heat is attributed to oxidation of tissue in connection with involution of the uterus, to the small wounds generally present in the genital tract, and to disturbances associated with commencing lactation.

PULSE.—After labor the pulse usually falls from 90 or 100 to 60 or 50, and, in exceptional cases, even lower. This slow pulse may last from three to seven days, and is regarded as a favorable indication, while, on the contrary, a rapid pulse is deemed an omen of unwelcome import.

Various hypotheses have been advanced in explanation of this clinical fact. Some ascribe it to increased arterial tension in consequence of the sudden arrest of the circulation in the uterus; others to diminished arterial tension, and still others to the complete and grateful rest—the pervading calm which succeeds the storm.

LOCHIA.—The lochia is a term applied to the liquid waste discharged from the uterus after delivery. The flow generally continues, in diminishing quantity and changing quality, for two, three, or four weeks. Exceptionally it ceases after only a few days. At first it is composed principally of blood which oozes or flows from the placental site, and serves to wash away particles or shreds of membrane, clots, and some of the various products of degeneration. As the blood-corpuscles in the lochia gradually decrease, the appearance changes from red to a pale greenish or yellowish hue, and, finally, it resembles a clear, albuminous liquid.

The odor is peculiar and more or less offensive, though under normal circumstances it should never be putrefactive or indicative of organic decomposition. Not infrequently the flow is suspended for a few hours, or is greatly diminished about the time the secretion of milk commences. Early suppression is not regarded as necessarily a dangerous symptom, but its sudden subsidence may be associated with grave pathological complications. If fetor or suppression be accompanied by a quickened pulse and an elevated temperature, it may possess important significance, and it demands measures of treatment to be considered hereafter; otherwise, warm fomentations or turpentine stupes to the hypogastrium, or the warm vaginal douche, will usually suffice to restore it. A decidedly offensive odor requires for its correction antiseptic vaginal injections: about two drachms of carbolic acid to a pint of warm water, or a watery solution of the corrosive chloride of mercury—one part to two or three thousand parts—every eight, twelve, or twenty-four hours, is usually effective. Two or three pints of either solution may be used.

Of recent years antiseptic measures have been given a much more prominent position in the management of puerperal patients than formerly. Antiseptic vaginal injections are now recommended and employed by some obstetric practitioners in every case, and even uterine injections are advocated. The extreme views entertained by some really eminent authorities, in reference to the employment of antisepsis during and subsequent to labor, border closely upon the absurd, and do not represent the conservative sentiment or the practice of the great mass of successful physicians throughout the country.

Without definite indications for their use, uterine injections should be condemned as dangerous, and even vaginal injections, while free from positive danger, as a routine procedure in private practice, under usual conditions, are unnecessary and had better be omitted. With fairly good sanitary surroundings, the vast majority of women recover without a ripple from the effects of simple labor, and a physiological lochial discharge, like physiological menstruation, may be left to itself, thereby avoiding the risks and the annoyance of uncalled-for manipulation of the genital organs.

The so-called antiseptic pad is not requisite. The discharges may be received with perfect confidence upon clean cloths. The external parts should be bathed or douched with warm or hot water, containing a little carbolic acid, sufficiently often to maintain a state of cleanliness. Sponges should give place to cloths or absorbent cotton.

Any fissures or abrasions about the vaginal outlet may be treated by the application of carbolized oil or iodoform ointment.

In the event that the lochia retains, unduly, its sanguineous character, the state of the uterus, as to the progress of involution, should be ascertained.

THE BLADDER should be emptied six or eight hours after labor, the patient remaining on her back, and using, if practicable, a bed-pan. In some cases—more particularly after difficult and protracted labors, and in nervous subjects—there is inability to pass urine for the first two or three days. The removal of the accustomed pressure from the bladder, the flaccid state of the abdominal parietes, the tumefaction of the urethra and of the meatus on account of prolonged pressure, or from mechanical injury, over-distention, and the enforced recumbent position, explain this difficulty. Change from the horizontal to a sitting or kneeling posture, small doses of ergot, and warm cloths to the hypogastrium and vulva, will generally secure relief. Occasionally the catheter may be required, though it is better not to be officious with instruments in such cases. An ordinary gum-elastic or a soft-rubber catheter is to be preferred to any rigid metal instrument. Care should be taken not to introduce into the bladder, by means of the catheter, any of the secretions or discharges contained within the vagina, for fear of setting up a cystitis.

THE BOWELS are almost invariably inactive after delivery, and in the event that spontaneous evacuation does not occur, the comfort of the patient will ordinarily demand some gentle laxative about the third or fourth day, to be repeated, as required, every two or three days during her confinement to bed. The various saline aperients answer this purpose well. A most acceptable and agreeable substitute for the nauseous dose of castor-oil, which has the sanction of custom and authority, is the solution of citrate of magnesia. A simple enema of tepid water is preferred by some practitioners, and, in many instances, meets every indication. Calomel and other mild cathartics have their advocates, and their appropriate places among useful remedies that may be employed.

THE UTERUS.—Immediately after the expulsion of the placenta, the uterus, if firmly contracted, may be felt like a hard, globular body resting above the pubes. The excessive development of the organ incident to pregnancy and parturition is gradually reduced, by a process of fatty degeneration, and in about two months, unless checked by some untoward circumstance, its normal dimensions are attained. At the end of a fortnight after delivery, it has retracted below the level of the pubic bones; its weight has decreased from thirty or thirty-five ounces to about twelve ounces, and its cavity measures only about four and a half inches.[4] Tonic contraction causes intimate approximation of its tissues, and effectually closes the sinuses and open vessels, shuts out atmospheric air, prevents the formation of clots, and promotes involution. The mucous membrane is soon restored and involution is complete.

THE VAGINA, after the enormous stretching to which it is necessarily subjected during the passage through it of the child, slowly regains its tone and elasticity, though it remains permanently wider than in the virgin state. All abrasions and superficial ruptures heal; tumefaction subsides, and within three or four weeks its normal condition is reached.

THE PERINEUM.—Perineal rupture occurring during labor may unfavorably influence involution. Fissures of the fourchette or slight lacerations of the perineum usually heal if left to themselves, or, at all events, give rise to no subsequent inconvenience. More extensive lacerations should be immediately repaired. Three or four sutures, passed deeply enough to secure close approximation of the ruptured surfaces, may be necessary. The simple interrupted suture, made of catgut or silver wire, or, in the absence of these, of silk, is all that is required.

THE BREASTS.—About the third or fourth day the physiological activity of the breasts begins to attract attention. The secretion of milk becomes active. Prior to that time, a fluid, differing from milk both in composition and appearance, is secreted. This fluid is known as colostrum, and it is believed to possess laxative properties—a provision of nature designed to clear the child's bowels of the meconium.

The mammæ may be turgid, nodular, and painful, and more or less general disturbance may be associated with this local condition. The pain sometimes radiates from the breasts across the chest and down the arms. The axillary glands may also become sensitive and enlarged.

For the sake of the child, great care should be taken to preserve the integrity of this function. If the breasts are pendulous, they should be supported by some appropriate device. The accumulated milk, which contributes to the pressure from within, should, when the child is not

equal to the demand, be gently drawn from the ducts by the lips of the nurse while the breast is supported between her hands, moderate friction or expression being at the same time made on the gland. Some nurses are very skilful in drawing breasts, and depletion by this means is preferable to the use of the breast-pump, which is attended with some risk. Puppies have been called into requisition for the same purpose.

Topical applications of belladonna, for its anodyne effect, are useful. Anointing the breasts with olive-oil is recommended. If the milk should not be required for the child, belladonna, iodide of potassium, and phytolacca decandra may be given internally. If, however, the child is to be nursed, great circumspection should be observed in the use of this class of remedies, on account of the liability of permanently arresting the secretion. Quinine is frequently indicated.

The constitutional excitement which usually attends painfully distended breasts, and which is marked by headache, flushed face, anorexia, coated tongue, thirst, slight increase of temperature, and some quickening of the pulse, was formerly described as milk-fever.

The very existence of such a disease is now denied, and it is characterized as "a vague tradition that does not rest upon classic observation." Certainly, it is now regarded as of rare occurrence.

According to Galabin,[4] a rise of temperature about the third day is often due to some transient septic or traumatic disturbance; but he adds that it may be caused about this time by irritation and tension, or by slight inflammation of the breasts.

Playfair[5] says it has been immensely exaggerated. It is rare in these days, since starving of puerperal patients is no longer considered necessary. There does not seem to be any sufficient reason for referring it, even when tolerably well marked, to septicæmia. The relief which attends the emptying of the breasts seems sufficient to prove its connection with lactation, and the discomfort which is necessarily associated with the swollen and turgid mammæ is, of itself, quite sufficient to explain it.

Barker[1] does not regard the prevailing opinion respecting this question as change in sentiment merely, or as dependent upon information derived from the more general use of the clinical thermometer, but to the fact that there is an actual decline in the occurrence of a veritable disorder in consequence of improved hygienic management—in securing rest, in giving good nourishment, and in the early application of the child to the breast.

The nipple, in primiparæ, should be shaped and developed by drawing it into an ordinary glass nipple-shield, or into the neck of a suitable bottle, which may have the contained air rarefied by filling it with hot water and emptying it immediately before it is applied. As the bottle cools, the nipple is forced into its mouth by atmospheric pressure.

Sensitive, abraded, or fissured nipples sometimes demand attention. Sponging with cold water and thorough drying after every application of the child to the breast may prevent or relieve these troubles. Sometimes astringent applications, or the solid nitrate of silver in the case of obstinate fissures, are required, or the habitual use of a nipple-shield may be necessary. The shield should have a flaring glass base and a rubber mouth-piece. Temporary withdrawal of the child from the breast may become necessary.

Deficient flow of milk, known as agalactia, or excessive secretion, galactorrhœa, may require interference. The former condition may best be treated by attention to the hygiene of the woman, and by improving her nutrition. Milk is especially serviceable for this purpose, and its good effect is enhanced by the addition of a little brandy or whiskey, if the spirit agrees with the patient, and is not otherwise contra-indicated. Porter, ale, malt-extract, or beer is used by some persons with satisfaction. Of course, organic defects in the gland are beyond the reach of these means. In galactorrhœa the milk is apt to be of poor quality, and invigorating measures of treatment are usually indicated. Certain drugs, especially belladonna, iodide of potassium, and phytolacca decandra, are reputed to possess the property of directly decreasing the lacteal secretion. These may be cautiously used, when necessary, in connection with general hygienic management. The amount of liquid ingested should be restricted as much as possible, and hydragogue laxatives may be advantageously employed.

The Binder.—The use of the traditional binder after delivery appears to be more a matter of comfort than of necessity, and as most women prefer it there can certainly be no valid objection to its employment, provided it be properly applied. It is very doubtful if it contributes to the maintenance of uterine contraction, or if it tends to the preservation of a symmetrical figure; but it does afford support to the stretched abdominal walls, and does prevent disagreeable sagging of the abdomen pending the restoration of normal muscular contractility.

Rest for a few hours after labor is very important, and very grateful to the patient. The room should be pleasantly shaded, avoiding a glare of light on the one hand, and darkness on the other. Quiet should be enjoined, and every facility for undisturbed repose afforded. If necessary an opiate may be administered.

The time at which a puerperal woman may leave her bed with safety cannot be fixed by any arbitrary rule. It varies with the individual, and depends, in part, upon her recuperative energy, and the absence of retarding complications, the severity of the labor, and the general condition of the patient, irrespective of puerperal experiences.

Attempts to prescribe a definite period of confinement show the futility of all such efforts. One writer (White) advocates sitting up a few hours after labor. Others (Goodell, Solovieff) fix upon the second day—allowing their patients to sit up while the bed is being made, and so on until the fifth day, when, if so disposed, they may get up and dress themselves. Others[6] (Avrard, Chapman) say the puerperal woman must keep her bed for three or four weeks—often longer, never less.

Here, as elsewhere, sound common-sense ought to prevail. This, joined with experience, teaches that the majority of puerperal women, under favorable circumstances, may leave their beds without detriment from the tenth to the fifteenth day, though they should keep their rooms for three or four weeks, and avoid physical exertion for even a longer period.

The Food of the puerperal woman should be sufficient in quantity, and suitable as to quality. The most extreme and unreasonable views are entertained upon both sides of the question of dietetics. Because some women have been starved, others, forsooth, need not be glutted. The golden mean—the middle course is safe. It should be remembered that the appetite and the digestion are impaired by the fatigue and anxiety of labor, and by subsequent confinement to bed. The stomach should not be overtaxed, but adequate support should be secured. Liquid food, at first, is preferable. Milk, tea, animal broths, and eggs may be gradually supplemented as convalescence progresses. The influence of the mother's diet upon the nursing infant, through the medium of her milk, should not be overlooked.

The lying-in chamber should be well ventilated and comfortably warmed in winter. All soiled clothing, excretions, and discharges from the patient must be promptly removed. No disinfectant or deodorizer can take the place of fresh air, which, without involving exposure, should be freely supplied.

Good nursing is of inestimable advantage to the patient, and a source of great satisfaction and comfort to the physician. A quiet, gentle, intelligent, and not over-officious attendant contributes largely to the successful conduct of a case, and to its auspicious issue.

Pathological Complications.—The normal progress of puerperal convalescence may be interrupted by the intercurrent development of a number of more or less grave complications, some of which merely retard improvement and delay recovery, others, of more serious import, jeopardize the existence or actually terminate the life of the patient, who has survived the manifold perils of pregnancy and parturition.

HÆMORRHAGE.—The hæmorrhages of the puerperal period are primary, or post-partum, and secondary, or puerperal. Post-partum hæmorrhage may occur immediately after the birth of the child and before the placenta is expelled, or it may follow the delivery of the placenta.

It is one of the most serious and alarming accidents to which the puerperal woman is exposed, and unless the medical attendant is at hand, and is prepared to act promptly and courageously, death may ensue in a few minutes. In post-partum hæmorrhage proper, the blood escapes from the open extremities of the uterine vessels, which are torn across by the separation of the placenta. These vessels are compressed, physiologically, by the firm contraction of the uterus, which effectually closes them, and they are further occluded by clots which, in the form of thrombi, seal up the ruptured ends.

The condition of the uterus which makes this form of hæmorrhage possible is imperfect contraction. There can be no hæmorrhage from the uterine vessels with complete, permanent contraction. There is no safety without it.

Any circumstance, whether functional inactivity, organic defect, emotional disturbance, or mechanical obstruction to firm closure of the uterus, acts as a cause and invites the occurrence of hæmorrhage. Likewise, any cause that so impresses the constitution of the blood as to prevent the formation of thrombi, and any condition that interferes with the circulation in such manner as to produce congestion of the uterus or of the peri-uterine structures, or any derangement of the heart's rhythmical action, predisposes to hæmorrhage and may occupy a direct causative relation to it.

If the flow should continue notwithstanding tonic uterine contraction, the probabilities are that it comes from some laceration of the uterus, cervix, vagina, or vulva, and thorough exploration will reveal its source.

The symptoms vary in severity, according to the suddenness and violence of the occurrence. In general there is pallor, faintness, vertigo, impairment or loss of vision, thirst, dyspnœa, gasping, and a weak, thready, sometimes imperceptible pulse. In extreme cases syncope and, possibly, convulsions speedily follow. There is generally a gush of blood from the vagina simultaneously with the occurrence of the first symptoms. The flow continues in a more or less copious stream until arrested. Occasionally there is no external appearance of the hæmorrhage, but the blood flows freely into the cavity of the womb, which becomes rapidly distended by its accumulation, and the same train of general symptoms is observed. This is denominated concealed hæmorrhage.

Fortunately, this terrible experience may be averted, except in very rare instances, by the skilful management of labor. The attention should be directed to securing tonic uterine contraction as a prophylactic, and also as a curative means when the hæmorrhage occurs. External pressure and manipulation with the hand over the fundus, and ergot subcutaneously and by the mouth, may suffice for this purpose. Two grains of ergotine dissolved in water, or one drachm of the fluid extract of ergot, may be used for the hypodermatic injection. If immediate contraction does not follow the pressure upon the fundus, pass the other hand into the vagina, and, if necessary, into the uterus—continuing to grasp the fundus—and extract all clots or retained fragments of secundines; or, if the placenta has not been expelled, it must be removed, after gently separating any adhesions that may be found to exist. In the event this manipulation does not cause contraction, pass into the uterine cavity a piece of ice about the size of a hen's egg, a pared lemon, gashed about the surface to admit the ready expression of the juice, or a clean handkerchief or a sponge saturated with vinegar. Bimanual compression, whereby the uterus is anteflexed, may serve as a valuable temporary expedient. The injection into the womb of hot water is an efficient resource. This may be readily done by passing the nozzle of a rubber-ball syringe into the cavity, special care being taken to expel all the air from the instrument. The returning stream may be received in a bed-pan. The child, meanwhile, should be put to the breast, and an opiate to allay agitation is usually indicated. Some advantage is derived from the ingestion of hot fluids, either milk, tea, or water.

Injecting the cavity, or swabbing the internal surface of the uterus with styptics, remains as a last resort. The practice is not free from danger, but under the pressure of an immediate and urgent demand it is certainly justifiable. The tincture of iodine is to be preferred for this purpose. It is in effect both an active antiseptic and a styptic. The officinal tincture may be diluted with two to four parts of water, or used, if considered desirable, in full strength. The solutions of persulphate, the subsulphate, or the perchloride of iron—one part to five of water—are powerful styptics, and may be used instead of the iodine; but the hard, disagreeable clots which the iron solutions produce constitute a serious objection to their employment.

The womb should be empty when the styptic applications are made. If practicable, it is well to wash it out with hot water, to be immediately followed by swabbing its surface, or by the injection of from one to six or eight ounces of the styptic solution.

After the cessation of the hæmorrhage, stimulants to sustain the circulation and to prevent syncope may be cautiously administered. The head should be kept low. If necessary, the foot of the bed may be raised. Absolute quiet in the recumbent posture should be assiduously maintained. If the loss of blood has been great, compression of the aorta or bandaging the limbs for several hours has been recommended. In extreme cases successful resort has been had to transfusion. Arterial and venous blood, saline solutions, and milk are thus used.

Arterial blood may be conveyed through the medium of a connecting tube and cannula, from the dorsalis pedis artery of the donor to the corresponding artery of the patient. Venous blood may be obtained from the median basilic, or from other superficial veins, and conducted by the same apparatus into a vein of the patient; or venous blood may be drawn, defibrinated, and introduced into the patient's veins by means of a funnel, tube, and cannula. Lamb's blood has been proposed as a substitute for human blood.

A solution of the chloride of sodium—one drachm to a pint of water at a temperature of 100° F., to which thirty grains of bicarbonate of sodium may be added—has been recommended for injection into the veins in lieu of blood. A quart or more of this solution may be thrown very slowly into one of the veins of the arm. It fills the empty vessels, but does not nourish the vital organs. Its reviving effect is apt to be only transitory.

Milk, proposed by Dr. T. G. Thomas, to be used in the same manner, has been employed with fair success. Good results have been reported from the hypodermatic injection of the warm saline solution, as has been proposed in the collapse from cholera.

The practical value of transfusion as a remedy in puerperal hæmorrhages is variously estimated. There are many impediments to its successful employment, especially in private practice.

Landis[7] tersely sums up his conclusions in reference to the utility of the measure, by declaring: "If the patient is able to endure the operation, she does not need it; if she does need it, she is too weak to bear it."

The introduction of the saline solution or of the milk is not attended with such difficulties as are inseparable from the transfusion of blood.

Puerperal or *Secondary Post-partum Hæmorrhage* may occur at any time from six hours to three or four weeks after delivery. The causes are substantially the same as in primary hæmorrhage. This event need not be feared in a healthy subject, with a uterus completely emptied, free from disease, and which is firmly and continuously contracted.

The recognized causes of puerperal hæmorrhage are: Albuminuria, purpura, puerperal poison, malaria, emotional excitement, secondary inertia, uterine fibroids and polypi, adhesions, retained coagula and placental fragments, inflammatory ulceration and severe laceration or malignant disease of the cervix, partial or complete in-

version of the uterus, pelvic cellulitis, metritis, perimetritis, uterine displacements, subinvolution, distended bladder and rectum, premature sexual intercourse, functional hepatic derangement, cervical thrombus, coughing, vomiting, and physical effort.[8]

These causes may all be grouped in three classes: 1, Impoverished blood; 2, mechanical impediment to uterine contraction; 3, disturbances of the circulation, either general or local.

In the management of "secondary puerperal metrorrhagia" the essential prophylactic means consist in the correct conduct of labor and a proper puerperal hygiene. If the flow should be profuse, energetic measures are required, but if the discharge should be only slight yet continuous, less active treatment will suffice.

The removal of the offending cause, when practicable, is the prime requisite. This consists in the withdrawal from the uterine cavity of any substance that may prevent physiological closure of the womb; the correction of any constitutional vice that may be present, and of any functional impediment to the integrity of the circulation.

The cervix may have retracted, so that dilatation by means of sponge-tents may be necessary to make intra-uterine exploration and the removal of any foreign material possible.

The hand laid upon the abdomen will reveal the state of the uterus as to contraction or relaxation. When compression is indicated, it should be made by grasping the fundus, aided, if necessary, by passing two fingers of the other hand into the vagina and exerting bimanual pressure. The vaginal tampon is not trustworthy, especially soon after delivery. It may prevent the external flow, but possibly, only by converting it into concealed hæmorrhage. Barker[1] recommends the cervical tampon, unless the os is patulous, allowing it to remain six or eight hours, and guarding against distention of the uterus by a compress over the hypogastrium, secured by a firmly applied binder. He has used the sponge-tent as a cervical tampon successfully on the third day. In any event, he confidently endorses the value of an injection into the rectum of one ounce of the oil of turpentine and half an ounce of olive-oil, to be retained as long as possible.

The injection into the uterus of hot water or the application of the styptic solutions, as recommended in primary hæmorrhage, may be demanded. Care must be taken, however, to secure a prompt return of the injected fluid and to avoid the introduction of air.

Ergot, quinine, and opium, with, perhaps, digitalis and strychnine, and stimulants, have their appropriate places in the management of these cases. In threatened collapse the hypodermatic injection of whiskey or ether may be necessary, on account of the importance of securing the stimulant effect promptly, and in consequence, possibly, of vomiting, and of the functional inactivity of the stomach. The advantages of position, of undisturbed repose, of a thoroughly digestible but sustaining diet, should be secured to the patient.

Faradic electricity has been successfully used to induce uterine contraction, and it would be entirely appropriate in either form of post-partum hæmorrhage, but the battery necessary for its production is seldom at hand in the emergency. If it is employed, one electrode should be applied over the fundus, and the hand, probably already in the vagina or in the uterus, may be utilized as the other pole by placing the second electrode in contact with the arm or forearm of the operator.

Puerperal Fever.—The most formidable complication of the lying-in period is the disease known as puerperal fever—a term which has been a familiar landmark in medical nomenclature for more than a century and a half, and with which it would be difficult to dispense in the absence of an acceptable and comprehensive substitute.

The nature of this affection has served as the basis of many vehement controversies, and it still challenges the most earnest discussions between the advocates of the different doctrines which are maintained respecting its character.

It has been ascribed to retention of the lochia, to metastasis of the milk, to failure on the part of the excretory organs to eliminate effete material, to metritis, to erysipelas, etc. But these and other theories, proposed from time to time, have, one after another, been abandoned, and now two prominent doctrines are upheld. These are:

First, the doctrine of a fever peculiar to puerperal women, the symptoms of which are essential and are not the consequence of any local lesions; a zymotic disease resulting from some unknown blood-changes, of the specific cause of which changes we are ignorant, but the determining cause of which may be epidemic influence, contagion, infection, or probably nosocomial malaria.[1]

Second, the doctrine that puerperal fever is puerperal septicæmia, analogous to, if not identical with, the so-called surgical fever, modified by the physiological state of the subject, and usually associated with various local inflammatory lesions.

While the theory of septicæmia is not free from difficulties, it is unmistakably evident that the tendency of modern thought, in the light of more recent researches, is strongly toward the acceptance of this doctrine, and that puerperal fever is now generally regarded as an infectious and contagious disease, produced, for the most part, by the absorption of septic matter through wounds in the genital tract, caused by the separation of the decidua and by violence inflicted during the act of parturition, and usually complicating, or complicated by, inflammatory lesions within the pelvis or the abdomen, which constitute, in their different forms, the several varieties of this affection.

The acute inflammatory lesions referred to as usually coexistent with the blood-poisoning, manifest themselves primarily as vaginitis, endometritis, metritis, pelvic cellulitis, pelvic peritonitis, general peritonitis, phlebitis, and lymphangitis, and secondarily, in the serous membranes, as pleuritis, pericarditis, and meningitis and also in purulent inflammation of the joints. Pyæmia and circumscribed inflammation of the subcutaneous areolar tissue, terminating by resolution or by suppuration, are among the secondary affections.

Inflammation of the genital mucous membrane may be superficial—catarrhal merely, or granular—and it may spread from the endometrium along the Fallopian tubes, producing salpingitis; and by extending still farther, may involve the peritoneum and set up a more or less diffused peritonitis; or the inflammatory action may go deeper, resulting in ulceration. These ulcers may assume a diphtheritic form, especially around the vaginal outlet, and round bacteria or micrococci are plentifully found in them. With vaginitis are associated painful micturition and defecation.

In metritis, or inflammation of the uterine parenchyma, the tissues become soft and relaxed, and involution is retarded or arrested. The muscular wall is œdematous, or the connective tissue may be filled with a sero-purulent fluid, or small collections of pus may occur. The margins of any fissures about the cervix may become sloughy or gangrenous. The uterine veins and lymphatics most likely share in the morbid process in operation around them. The inflamed veins are thickened, and contain lymph and, rarely, pus. The lymphatics are frequently loaded with pus, and upon cross-section present to the eye the appearance of intramuscular abscesses.

The cellular tissue in immediate proximity to the uterus may be invaded, giving rise to what is known as parametritis, or the inflammatory action may extend to more remote layers of connective tissue within the pelvis, thus establishing pelvic cellulitis. More or less swelling occurs, caused by the effusion of serum and, later, by the exudation of lymph. Suppuration may result, with, possibly, burrowing of pus and the formation of fistulous openings, or the inflammatory products may be absorbed, leaving usually some induration. In the more severe septic forms of cellulitis the exudation degenerates into a turbid, purulent fluid which fills the interspaces of the tissues.

Peritonitis may be limited to that portion of the peritoneum within the pelvis—pelvic peritonitis or perimetritis—or the inflammation may invade the abdominal cavity, resulting in general or diffused peritonitis, which is usually a prominent, and almost a constant, feature of puerperal fever. Tympanitic distention of the intestines is a conspicuous and early symptom. In mild cases the exuded lymph either floats in the form of flakes in the effused serum or it is spread over the surface of the abdominal viscera. The peritoneum is lustreless, roughened, and ecchymosed, and in the severer types contains more or less pus.

The inflammatory affections above described may occur as independent lesions, associated with puerperal processes, but without clinical evidence of septic infection; and, on the other hand, septicæmia may run its course in rapidly fatal cases and no appreciable disease of the genital organs or of the peritoneum be detected by ordinary methods of investigation. Nevertheless, as remarked by Playfair,[5] there is little doubt but that in these intense cases profound pathological changes exist in the form of alteration of the blood and degeneration of tissue.

If the disease should be protracted, pyæmia is apt to be developed, the prominent symptoms of which are frequently recurring rigors, high temperature, profuse sweating, and localized inflammations and abscesses. Pyæmic abscesses in the lungs and in the kidneys frequently result from emboli, formed by the disintegration of an infected venous thrombus.

The appreciable symptoms of puerperal fever are usually manifest on the third day after labor. Exceptionally, they may be observed on the second, or be delayed as late as the seventh day. The attack may be very acute in its symptoms and course, or it may be less intense—a form sometimes described as subacute. The onset is frequently insidious. It may be indicated by a sharp chill, a slight rigor, or only by chilly sensations. The pulse runs up to 100, 120, or 150, or even higher. The temperature mounts to 102°, 104°, or 106°. The lochia generally becomes offensive and is diminished in quantity, or is suspended. The secretion of the milk may be prevented or, if it has commenced, is often, though not always, arrested; abdominal pain and tenderness are usually present, though they may be slight and are occasionally wanting. Constipation may at first be present, and be succeeded by diarrhœa. The bowels are distended with flatus. Tympanites sometimes constitutes the most severe symptom. Nausea and vomiting are apt to occur. The vomiting and diarrhœa may seriously hamper efforts to nourish the patient, and thus contribute directly and indirectly toward prostration. Some cases are notably marked by depression, presenting throughout an asthenic type, sometimes called typhoid. In this form low delirium is apt to be developed at night, and pulmonary complications are more likely to occur.

Fatal cases of the intense variety usually run their course in a week. Local complications modify attacks by interjecting their own peculiar symptoms among the general or constitutional symptoms. In some cases one train of symptoms predominates, in other cases another set of symptoms is more prominent. In grave cases an anxious expression of countenance is observed, but it is usually unaccompanied by fear of impending danger.

In the less intense or the subacute form of the disease the symptoms are not so active. It develops later, usually lasts longer, and may be very mild in its manifestations. Some cases are characterized by a succession of chills at irregular periods, which may, in spite of all treatment, continue to recur over and over for several weeks. These symptoms are probably indicative of mild pyæmia.

The different pelvic inflammations which belong to the clinical history of puerperal fever are not always to be discriminated. Several frequently coexist, so as to render isolation and differentiation of the individual lesions impossible.

The cause or causes of puerperal fever, whatever they may be, are generally admitted to be influenced by the physiological condition of the puerperal woman. The state of the blood, of the nervous system, and of the genital organs form important elements in estimating correctly the effects of pathogenic agencies. Most authorities agree upon the possibility of self-infection, and all concur in the certainty of infection from without.

"Puerperal fever is puerperal septicæmia," is the concisely expressed creed of Thomas,[9] who adds that the essence of the disorder is a poison absorbed into the blood of the parturient woman through some solution of continuity. Whatever may be the character of this poison, we know that there are two, and only two, methods by which it can reach the parturient tract and exert its baneful influence. First, it may be carried into the vagina by the atmosphere, in which it floats as an impalpable substance; and second, it may be carried to any part of the genital tract by the fingers of the doctor or nurse, by sponges, cloths, towels, and instruments, and by the clothing of the patient.

After reviewing the pathology of puerperal fever, Galabin[4] concludes that the affections which have been included under the title of puerperal fever, though they have a common element in the reception of some poison, cannot be reduced to a uniform pathology, but are various in their nature and origin. According to the new nomenclature of the Royal College of Physicians of London, the title puerperal fever is to be discarded, and the diseases are to be classed, according to their most prominent character, as puerperal peritonitis, puerperal cellulitis, puerperal septicæmia, puerperal pyæmia, and the like. Galabin makes the following classification: 1. Endogenetic toxæmia, in which noxious material is produced in the blood itself, or retained in it through deficient action of the organs of excretion. 2. Septic intoxication, in which a chemical poison only is absorbed. 3. Septic infection, in which organisms multiply in the blood or in the tissues, or in both.

Septic intoxication and septic infection cannot generally be practically distinguished.

Lusk,[2] who regards puerperal fever as an infectious disease due, as a rule, to septic inoculation of fresh wounds in the genital tract, says it seems impossible to make all of the facts coincide with the theory that the genitalia of the puerperal woman are the exclusive point of entry of infectious materials into the system. The deleterious materials may find other channels of entering the system than wounded surfaces; and while he cannot go as far as Tarnier, who believes that it is by the lungs that poisoning often, if not always, occurs, it does not seem time to give up the idea that the respiratory and digestive tracts may allow the passage of material of a specific character. He attributes to the lochial discharge much of the unhealthfulness of maternity wards.

"The maligned lochia" is an expression used by Barker,[10] who, in the form of a query, intimates that nature has wisely arranged to furnish the best fluid for constantly bathing the bruised and lacerated tissues of the parturient canal.

A number of different poisons or causes, but no specific puerperal poison, and no specific puerperal fever, represents the views of Leishman.[11]

Parvin[6] utterly repudiates the doctrine of the autogenesis of puerperal fever. He considers it a confession of ignorance, and the very pessimism of obstetric medicine. But while decomposing organic matter in the vagina or uterus does not create the disease, it furnishes a nidus for the lodgement and propagation of septic germs.

Playfair[5] holds that the assumption of a puerperal miasm is not necessary, and that the most practical division of the subject is into cases in which the septic matter originates within the patient, so that she infects herself, the disease being then properly autogenetic; and into those in which the septic matter is conveyed from without, and brought into contact with absorptive surfaces in the generative tract, the disease then being heterogenetic.

Barnes[3] declares that puerperal fever is fever in a puerpera, and that we must abandon the vain attempt to

find one definite puerperal fever, and recognize the clinical truth that there are puerperal fevers—autogenetic fevers, resulting from the retention of excretory, and the absorption of septic, matter; and heterogenetic fevers, due to the reception of extraneous poisons of cadaveric, puerperal, or obscure animal origin, or that can be traced to certain zymotic influences.

The influence of bacteria in the production of puerperal fever has not been definitely established. Authorities differ widely in their estimate of the importance of microbes as an essential agency—some affirming, others denying, their potency. There is unquestionable evidence, however, to sustain the fact of their presence in the form of round bodies, or micrococci, which have been found abundantly, either singly or united in chains or clusters, in the tissues and in some of the fluids of the subjects of puerperal and of surgical septicæmia and pyæmia. Micrococci are also found in other diseases, but it does not follow, because of similar microscopical appearance, that they all possess pathogenic identity.

The view is generally accepted that diseases clinically inseparable from puerperal fever may originate by exposure to the poisons or to the products of certain zymotic diseases—notably scarlet fever, diphtheria, erysipelas, typhus, and typhoid fever—and also by contact, direct or indirect, with suppurating wounds, decomposing animal matter, and, possibly, to the influence of sewer-gas and of other impure air; though it appears to be certain that exposure to these poisons does not invariably produce this disease, and, moreover, according to the observation of Playfair,[5] any zymotic disease may attack a newly delivered woman and run its characteristic course without any peculiar intensity.

While puerperal fever is believed to be both contagious and infectious, in the sense that it may be communicated by a virus or by a miasm—by a palpable or by an impalpable product—it is more than probable that different forms vary in respect to their communicability, and that some forms of the disease are much more readily communicated to susceptible subjects than are others.

The treatment of puerperal fever is prophylactic, local, and constitutional. The preventive treatment has reference to the judicious management of labor, to the strict observance of a conservative and sound puerperal hygiene, and to the conduct of the medical attendant and the nurse in relation to the conveyance of any poison to the patient. Scrupulous cleanliness of the hands, instruments, clothing, bedding, and of everything surrounding or that may come into contact with the puerperal woman, is of paramount importance. With absolute cleanliness, the usefulness of antisepsis shrinks into comparatively narrow limits. Nevertheless, it is a simple matter to use the bichloride-of-mercury or the carbolic-acid solutions in washing the hands and in cleansing the instruments, and it is certain, with ordinary care, that no harm will be done, unless, perchance, the antiseptic should be relied upon as a substitute for, and to the exclusion of, that uncompromising cleanliness which is herein earnestly advocated, and which must precede or accompany antisepsis if we would not invite disappointment.

The duty of the physician in respect to contagious diseases—to those diseases that are supposed to hold some relation to the causation of puerperal fever—and to septic material of all kinds, is plain. The danger of infecting his patient should deter him from attending her directly after contact with such poisons, or when closely confined with them. Of course, a physician engaged in general practice cannot refuse attendance upon obstetric cases every time he encounters infectious diseases or septic matter; yet the risks, under these circumstances, demand the observance of extraordinary precautions as to his person and his clothing.

Are antiseptic vaginal and uterine injections to be reckoned among legitimate preventive measures? If it should appear that they are in themselves harmless, then an affirmative answer may be given. If, on the other hand, their use involves a risk, even a slight risk, to the patient, the propriety of the procedure may be very seriously questioned.

Barker[10] says: "Antiseptic injections, both vaginal and intra-uterine, are of great service when the indications for their use are clearly shown by local signs or general symptoms; but they cannot be recommended with safety as a routine practice on theoretical grounds, as, for obvious reasons, they may be most detrimental in retarding the cicatrization of lesions and the other processes of normal convalescence, and are otherwise sometimes dangerous."

Thomas[10] admits that "the arguments which have been brought up against this practice (antiseptic vaginal injections every eight hours after labor), since I read my paper, have had great weight with me. I confess that I feel less firm upon this point than I did, and that in future I shall examine the question carefully before I determine to adhere to my plan." In regard to uterine injections, he deprecated the impression which seemed to prevail that he resorted to them with very little provocation, and adds: "No one could have striven more than I have done to keep within proper bounds the indiscriminate use of this dangerous but valuable resource."

Lusk[10] advocates antiseptic vaginal injections after normal labor in all cases, and uterine injections after difficult labor, where the hands or instruments have been introduced into the uterus, but says:[2] "I know that of late years there has been a strong reaction against the use of vaginal injections in normal childbed, but personally I have experienced none of the disagreeable effects ascribed to them. Indeed, both my hospital and private patients speak of them as soothing and grateful. I therefore have had no ground to discontinue them. That they are indispensable, I do not claim. They are no longer used in Vienna, in Prague, nor in the New York Maternity, and yet, none the less, their results have been in the highest degree satisfactory."

"At these institutions, however, vaginal disinfection is vigorously resorted to during and immediately subsequent to labor, and during childbed some form of antiseptic pad over the vulva is employed."

He adds: "Intra-uterine injections should be resorted to with great circumspection. They are not indicated by a simple rise of temperature, and, unless the infection proceeds from the uterine cavity—which is the exception—they are unnecessary."

Braun von Fernwald, in discussing prophylactic uterine injections, is quoted as saying: "We must protest against injections made by physicians into the uterine cavity; such meddlesomeness is more likely to do harm than good." Our author adds: "This corresponds to my own experience."

Galabin[4] advises antiseptic vaginal injections twice daily in all cases, but says of uterine irrigation: "Its indiscriminate use after all cases of labor has been found to be rather injurious than beneficial, and to increase rather than diminish the number of cases of septicæmia."

Parvin[6] thinks that, in the absence of any indication, vaginal injections are not necessary.

Playfair[5] advises antiseptic vaginal injections when the lochia is fetid, and thinks uterine injections should not be omitted in cases in which self-infection is possible; "and, indeed, when there is no reason to suspect a local focus of infection, the use of antiseptic lotions (intra-uterine injections) is advisable as a matter of precaution, since it can do no harm and is generally comforting to the patient."

Leishman[11] recommends antiseptic vaginal injections "if the fetor of the lochia is unusually great, or if the parts have been lacerated."

Barnes[3] says: "Wash out the uterus twice daily from the second day; should there be the slightest rise of temperature and pulse, the intra-uterine injection is imperative."

Measured by the rule above proposed, in the light of the evidence adduced, notwithstanding high authority to the contrary, the conclusion is inevitably reached, that under normal conditions, with fair sanitary surroundings, neither vaginal nor uterine injections are to be rec-

ommended as a routine practice, upon the theory of forestalling possible morbid developments, which may, if they should occur, produce a state of general septic toxæmia. But so soon as a probable diagnosis of commencing puerperal fever is made, based upon the presence of the usual initial symptoms—a sustained elevated temperature, associated with a quickened pulse, preceded, possibly, by a chill, and accompanied by pelvic pain or tenderness in the hypogastric region, tympanites, headache, flushed face, and general restlessness, with, perhaps, an offensive lochial discharge and arrested uterine involution, occurring about the third or fourth day—a warm vaginal injection of carbolic acid ʒ ij. to water Oj., or corrosive chloride of mercury one part to water 2,000 or 3,000 parts, or of tincture of iodine ʒ j. to water Oj., should be given and repeated two or three times daily. Meanwhile, agitation and pain should be subdued by an opiate. Morphine, hypodermatically, is usually the most available mode of administration. If the symptoms continue without abatement or with increased activity, the injection into the uterus of one of these antiseptic solutions should be practised, always by the medical attendant himself. The several dangers pertaining to this procedure—namely, shock, uterine hæmorrhage, injecting air or forcing the liquid into the peritoneal cavity—may generally be avoided by observing the utmost gentleness in all the manipulations, by carefully expelling all air from the injecting apparatus, and by warming the solution to from 100° to 105° F.

Great care should be taken to secure the ready egress of the injected fluid from the uterine cavity. If the os is patulous, as it usually is under these circumstances, this may be readily accomplished. For injecting the solution, either an irrigator or fountain syringe, or a hand-ball syringe, may be used.

The nozzle may be passed directly through the internal os, or it may be attached, through the medium of rubber tubing, to an ordinary gum-elastic catheter—or to some of the special tubes or catheters devised for this purpose—which should be carefully carried, while the liquid is gently flowing through it, into the womb. The return current may be received in a bed-pan, or conveyed by means of a rubber cloth, depending over the side of the bed, to a vessel on the floor. A thorough vaginal injection should first be given, to obviate the risk of carrying any septic matter from the vagina into the uterus. If frequent or very copious injections should become necessary, the danger of carbolic-acid or mercurial poisoning may be escaped by using simply warm water at first, to be followed, without withdrawing the tube, by a few ounces of the medicated liquid. The advisability of repeating this procedure once, twice, or thrice daily must depend upon the results obtained in the first trial. If improvement follows, it should be tentatively continued. If, on the contrary, unpleasant consequences ensue, it may be proper to abandon it at once.

Any fragment of the placenta or of the membranes, and any clot, that may remain in the uterus or the vagina should be carefully removed.

As an antipyretic and, possibly, as an antiferment, quinine is of great value in these cases. It should be given in full doses repeated twice daily, or, in some cases, it may be prescribed in smaller doses at shorter intervals. Salicylate of sodium and antipyrin may be employed as substitutes, if the quinine should fail or not be well borne. In some forms of the disease the remarkable tolerance of opium necessitates its free use to ease pain, quiet irritability, and secure sleep. Chloral, as a hypnotic, may sometimes be advantageously added. Alcohol is of pre-eminent service. It is usually tolerated in large doses. It reduces the temperature, prevents waste, and wards off asthenia. As a cardiac sedative, veratrum viride occupies the first rank. It may usually be given, noting the effect, in doses of five drops every three or four hours. It is not incompatible with opium or alcohol. It, too, is a conservator of the vital forces, besides contributing directly to the comfort of the patient. But let it be distinctly understood that neither veratrum nor other cardiac sedative is indicated if the rapid pulse is the result of a feeble heart. Frequent sponging of the body with cold or tepid water, or with alcohol, is beneficial. The cold bath and the cold pack are recommended for reducing bodily heat. They are difficult to administer in private practice, and are not entirely free from danger. Topical cold to the abdomen, as ice or cold-water coils, sometimes accomplish good if maintained for a number of hours; but in some cases the warm applications—poultices, turpentine stupes, etc.—are more comfortable and appear to act better. Ice to the head is sometimes employed.

To allay nausea, ice, iced champagne, and sinapisms to the epigastrium, are among the most trustworthy resources. Constipation, if it exists, may be overcome by enemata or laxatives cautiously given. Puncture of the intestines with a very fine, hollow needle, in distressing tympanites, has been successfully practised.

The diet should be nutritious and digestible; only liquids, as milk, animal broths, and gruel, should be allowed.

Any intercurrent local complication that may develop must be treated on general principles.

In estimating the value of any mode of treatment, it should be remembered that a large proportion of the febrile attacks of puerperal women pursue a favorable course and may be expected to terminate after several days, and even under the most discouraging assemblage of symptoms, hope of recovery should not be abandoned.

Phlegmasia dolens, or phlegmasia alba dolens, when it attacks the puerperal woman, appears, as a rule, during the second or third week after labor. The prominent local characteristics, when fully developed, are pain, swelling, a brawny hardness, and a glistening white appearance of the affected parts. It occurs commonly in one or both of the lower limbs, as a rule in one only, and exhibits a decided predilection for the left side. When both legs are invaded, the manifestations are not simultaneous, but the second is attacked from a day to a week later than the first. The disease sometimes occurs in the arms, and it has been observed in men. When the arms alone are involved, it is not often of puerperal origin. The shining whiteness of the skin gave rise to the popular appellation of "milk-leg," and suggested, no doubt, the early theory of milk metastasis.

The initial symptom of an attack may be a chill, followed by some reaction, with a sensation of heaviness of the limb, and a dull pain increased by motion. This may be preceded for a day or two by a feeling of great lassitude and depression. As the disease progresses the tenderness becomes extreme, and the degree of swelling may be enormous, the limb sometimes being double its natural size.

The swelling may commence in the thigh and extend downward, or it may first appear at the ankle and spread upward. The veins, like hard, knotted cords, may sometimes be felt in the beginning and during the subsidence of an attack. Other veins besides those of the extremities may also be the seat of the affection. The lochial discharge is frequently uninfluenced. The secretion of milk is generally diminished or arrested. In the ordinary course, after a week or ten days amendment takes place; the swelling gradually subsides, and the limb then pits on pressure; the exudation is absorbed, the circulation is restored, and muscular movements become possible. The usual duration of an attack is five or six weeks.

Under less favorable conditions, suppurative phlebitis may ensue, abscesses may develop, and extensive suppuration of the subcutaneous and intermuscular cellular tissue sometimes occurs. Occasionally the affected vein is permanently obliterated. A thrombus may undergo purulent softening and disintegration, and thus produce infected emboli, which may, in turn, originate metastatic abscesses at the points of lodgement in various parts of the body; or a large fragment of a thrombus, in consequence, possibly, of imprudent manipulation or premature use of the limb, may be carried by the circulation through the right side of the heart and produce sudden death by plugging the pulmonary artery.

The pathology of phlegmasia dolens has given rise to much controversy, which has served to develop numerous specious theories, none of which satisfactorily explains all of the morbid phenomena that are observed.

The doctrines of phlebitis, of venous thrombosis, and of inflammation or obstruction of the lymphatics, are all maintained. Some authorities now hold to phlebitis as the essential lesion, some to peripheral thrombosis, others to the obstruction of the lymphatic ducts and venous thrombosis combined—regarding phlebitis, when it is present, as secondary to the thrombus or to inflammation of the surrounding cellular tissue. The inflammation may be limited to the subcutaneous or to the intermuscular cellular tissue, or it may follow the perivascular connective tissue ; and secondary thrombosis and obstruction of the veins and lymphatics may result from the inflammatory thickening of their walls. A predisposition to this affection is established in puerperal subjects by the hyperinotic state of the blood, by the slow pulse, and by the occurrence of copious hæmorrhage. Varicose veins are also regarded as a predisposing cause.

The veins commonly involved are the iliac, femoral, crural, tibial, and peroneal. Venous thrombus may develop at any point in the course of a vein, or it may invade the veins by extension from the uterus.

A succession of chills occurring in the course of an attack of phlegmasia dolens, accompanied by high temperature, denotes some complication.

Absolute rest, with the leg slightly elevated, and with opium to relieve pain, are the principal indications for treatment. If constipation exists, laxatives or cathartics should be prescribed. Quinine in moderate or large doses is useful. Painting with tincture of iodine along the course of the affected vessels, if they can be traced, or over the entire surface of the limb, has been practised. Stimulating or anodyne liniments, applied with gentle friction after the most acute stage has passed, may be used in lieu of the iodine. The limb should be protected from the pressure of the bedclothing by a frame or cradle, and may be enveloped in cotton-batting or flannel, and covered by oil-silk.

As the swelling subsides some advantage is obtained from a well-applied roller-bandage, and the tincture of the chloride of iron may be administered. Blisters are not admissible, and leeches are not indicated, unless they be used with the hope of averting suppuration in some localized inflammation. If pus forms, it should be promptly evacuated.

In the employment of friction the possibility of dislodging a clot, or of separating a fragment from a disintegrating or softened thrombus, should be borne in mind. Absolute rest should be punctiliously maintained until every vestige of the swelling and of the tenderness has disappeared. The limb sometimes manifests a tendency to swell, after standing or walking, for several months, and is apt to be more or less impaired functionally for a considerable time. Great comfort and advantage may be derived from a close-fitting, long elastic stocking when the patient begins to walk about.

Venous and Arterial Thrombosis and Embolism, and Other Causes of Sudden Death.—The conditions which favor the occurrence of peripheral venous thrombosis invite similar formations in any part of the body, without association, necessarily, with the anatomical characteristics of phlegmasia dolens.

These clots may develop in the right ventricle and, extending into the pulmonary artery, cause death from asphyxia by arrest of the pulmonary circulation. Rarely, thrombi form in the arteries of the puerperal woman as they do in the veins, but circumstances are not so favorable to their development here.

A thrombus may undergo separation or disintegration, and the fragments thus formed, when caught up by the circulation and lodged in vessels of smaller calibre, constitute emboli, which, in turn, may become nuclei for fibrinous accretions and the consecutive development of other thrombi at the points of lodgement.

The pulmonary artery is not alone subject to this accident, but concretions from the left side of the heart may find their way into the systemic arteries, and especially the femoral, brachial, cerebral, and ophthalmic arteries may be thus occluded.

The symptoms depend, of course, upon the character, size, and location of the occluded vessel, and upon the suddenness with which the arrest of the circulation in it may be accomplished.

Sudden death sometimes overtakes the puerperal woman when all seems well. No intimation of the impending disaster is given, but after a brief struggle for breath, life becomes extinct.

This distressing result may be due, as has been shown, to pulmonary thrombosis or to pulmonary or cerebral embolism ; to cerebral hæmorrhage, or to hæmorrhage from the rupture of an aneurism or of an abdominal vessel ; to the entrance of air into the circulation, and to extreme syncope and shock.

Eclampsia.—Convulsions may occur during pregnancy, during labor, and immediately subsequent to, or within several hours after, delivery. It is the last class only that is to be included among the pathological complications of the puerperal state.

If the estimate of one case of convulsions to five hundred cases of labor is correct, and if the statistical results of Lohlein's investigations (quoted by Lusk[2]) are accepted, namely, that eighty-eight per cent. of puerperal convulsions occur in parturient patients, a post-partum convulsion must be an exceedingly rare event. It is fortunately true that such convulsions are very infrequent. From this reckoning, hysterical and epileptic convulsions, and the convulsions symptomatic of cerebral and meningeal lesions, are eliminated.

The convulsions of this period usually develop suddenly, though the foreshadowing symptoms may have been present and passed unobserved during pregnancy or parturition. The most constant premonitory symptoms and signs are headache, vertigo, low spirits, flashes of light, tinnitus aurium, nausea, vomiting, œdema of the face, albuminuria, and tube-casts.

The first convulsive movements may consist of slight twitching of the corners of the mouth or of the eyelids. Other voluntary muscles, especially those of the neck, trunk, and upper extremities, speedily become involved. The muscles of respiration are also apt to be affected. Consciousness is lost, and the respiration becomes irregular and stertorous. After lasting a few moments the muscular spasm relaxes, but the consequent sopor is usually protracted for from twenty or thirty minutes to several hours. A succession of convulsive seizures may occur, and alarming uterine hæmorrhages are sometimes among the unfortunate results.

The precise pathological nature of eclampsia has not been determined. Though defective renal elimination seems to be an important, if not the essential, factor. Changes in the circulation, nervous exhaustion incident to labor, morbid sensibility, and moral disturbances may act as exciting causes.

The prognosis is hopeful in proportion to the short duration, mildness, and infrequency of the seizures, and to the absence of grave fundamental lesions.

The treatment should be addressed to the prevention of the attack if any warning symptoms are present. The vicarious elimination of excretory products by the bowels and by the skin, and the use of calmative remedies, meet these indications. Venesection, so prompt and effective as a remedy in ante-partum convulsions, may sometimes be valuable in this form, but it should be resorted to with discretion.

Chloroform by inhalation is an indispensable and most efficient remedy. After the attack has subsided, the chloroform should be watchfully continued at intervals, and promptly renewed upon the least intimation of recurrence of a paroxysm. The hypodermatic use of morphine, the bromide of sodium or potassium, and chloral either by the mouth or by the rectum, are serviceable adjuncts. When an attack supervenes, the tongue should be guarded from injury by thrusting a cork or a roll of cloth between the teeth. The patient should also be prevented from otherwise injuring herself.

Puerperal Mania is usually developed, when it occurs, within the first two weeks after delivery.

In some cases the attack is foreshadowed by prodromic symptoms, lasting from a few hours only to several days, or its advent may be sudden and startling.

The manner is strikingly changed, and is marked either by excitement or by depression. The patient is sleepless, watchful, suspicious, talkative but incoherent, or maintains a moody silence. Irregular muscular movements and motiveless actions are generally noticed. The symptoms become more intense as full development is reached. The patient may be violent in speech and act. Profanity and vulgarity frequently characterize her expressions. Repeated attempts to leave the bed, to remove the clothing, and to inflict personal injury may be made. The emotional manifestations are sometimes of a pleasurable character, but at other times are profoundly depressed, and even suicide or infanticide may be attempted.

Attacks of puerperal mania are generally associated with a debilitated condition of the system, with defective nutrition, an impoverished condition of the blood, and some derangement of the cerebral circulation, resulting in a state either of anæmia or of congestion. When cerebral congestion is observed, it may possibly be a transient condition of an anæmic brain. Mania may be developed in connection with any of the severe puerperal lesions.

Heredity is an important element in the causation. Social condition and emotional perturbation are influential in its production.

The prognosis is generally favorable. It becomes less hopeful if the attack should be protracted beyond several weeks, and should drift into a state of settled melancholy. A fatal termination is generally due to some intercurrent affection, as metritis, peritonitis, or pneumonia.

Severe treatment is not admissible. Bloodletting and blisters are injurious. The indications point to quieting and supporting measures, and include the removal of any direct or reflex exciting cause. The hypodermatic use of morphine and of hyoscyamine is sometimes effective. Chloral and the bromides of potassium, sodium, and lithium are particularly trustworthy and valuable. These may be administered by the mouth or by the rectum. Severe catharsis is not required, but laxatives or gentle cathartics may sometimes be demanded for the purpose of overcoming constipation. Cold to the head may be tried when called for by undue heat.

An abundant, digestible, and nutritious diet is indispensable. Good nursing is a prime requisite. Tact and clear judgment in the nurse, combined with firmness and gentleness of manner, contribute largely toward the successful management of these cases.

Cardiac sedatives may be necessary on account of the development of inflammatory complications, which should be watched for and appropriately treated when they occur.

Mastitis or Mammitis, and Mammary Abscess.—Inflammation of the breasts, one or both, may be developed irrespective of lactation, but it is much more frequent during the functional activity of the gland, and the majority of cases occur between the first and fifth week after labor.

Inflammation may invade the subcutaneous cellular tissue, the glandular tissue, or the subglandular cellular tissue. In any of these situations it may terminate by resolution, or suppuration may ensue, giving rise, respectively, to subcutaneous or superficial abscess, to glandular or parenchymatous abscess, and to subglandular or deep mammary abscess. Any one of these forms of inflammation or suppuration may exist alone, or any two or all may exist simultaneously or consecutively.

The superficial variety resembles ordinary phlegmonous inflammation occurring in similar tissue elsewhere. It is marked by pain, heat, redness, and swelling, and is apt to end in suppuration, either as small boils around the nipple or as circumscribed abscesses upon any portion of the surface of the breast.

The deeper varieties are accompanied by considerable constitutional disturbance. Fever, headache, thirst, anorexia, and sometimes a rigor, characterize the commencement of an attack. In the glandular form the breasts are excessively tender, swollen, congested, distended, and painful. Lobular induration gives to the organ a lumpy or knotty feel. Several lobules are generally involved, and when suppuration occurs the abscesses are likely to be multiple—developing in some cases one after another, and extending through weeks or months. The lacteal secretion is suspended in the affected lobules. The milk-ducts are narrowed or closed. Pus may escape externally by ulceration through the skin, sometimes resulting in fistulæ, or it may penetrate one of the larger ducts and be discharged with the milk.

Subglandular cellulitis can seldom be detected with certainty until suppuration has taken place. The general symptoms are the same as those already enumerated. The pain is deep-seated and aching in character. The breast is greatly enlarged, though smooth and regular in outline. The axillary glands are usually swollen and tender, and movements of the arm which involve contraction of the pectoral muscles are exceedingly painful. The integument may become œdematous, but it is not congested or sensitive. If the accumulation of pus is considerable, the gland is lifted away from the chest-wall and floats upon the liquid base.

Attacks of mastitis are generally ascribed to cold, to blows or bruises upon the breast, emotional disturbances, obstruction of the lacteal ducts, and to inflammation of the nipples, extending along the milk-ducts or extending by the lymphatics to the deeper tissues.

Circumscribed cellulitis, whether superficial or deep, does not necessarily arrest the secretion of milk, even if localized suppuration occurs. If the inflammatory action is general, lactation is suspended, but the function is not destroyed unless sloughing or adhesions should permanently injure the secretory structures.

Superficial cellulitis may sometimes be arrested, at the very commencement, by the application of the tincture of iodine to the inflamed spot, and it may otherwise be treated like threatened abscess in any situation. If an abscess should form notwithstanding efforts to avoid it, recovery will be hastened by early opening in a line radiating from the nipple.

Constitutional treatment is indicated in the severer forms—sometimes in all. Opiates are frequently required for the relief of pain; laxatives or cathartics may be necessary. If the temperature or pulse-rate should run high, veratrum viride or some other cardiac sedative may be advantageously employed. When the excessive secretion and the accumulation of milk aggravate the pain or increase the risk of suppuration by pressure from within, belladonna or phytolacca decandra may be cautiously and tentatively used. Quinine is a valuable remedy, and should be given in full doses. In some anæmic and feeble subjects, a liberal, tonic, and supporting regimen is necessary.

The local treatment of the subglandular variety consists in rest and support of the breast. For this purpose, as well as for compression—which should be reserved in this form of abscess until after the evacuation of the pus—adhesive strips, a roller or a three-tailed bandage, applied as the tact, judgment, and experience of the physician may suggest, will accomplish the object sought. Topical medication is useless. So soon as pus is detected by palpation or by the introduction of a long exploring-needle, a free exit must be afforded at the lower part of the breast.

The treatment of the glandular form of mastitis is more satisfactory. In addition to the general means above recited, local treatment is very important. Nursing the child from the affected breast should be at once prohibited, but the engorgement of the breast must be overcome by rubbing from the base toward the apex. To lessen friction, a little olive-oil may be applied to the surface. Some persons prefer camphor, on account of its reputed property of reducing the secretion of milk. The lips of a nurse who understands the art of "draw-

ing breasts," applied over and around the nipple, will materially aid the process of expression. Repetition of this procedure, probably twice daily for several days, will be required.

The breasts should be supported and compressed either by skilfully applied adhesive strips, a bandage, or the compressed sponge. The topical use of belladonna is serviceable. Dry cold is recommended, though warm applications are, perhaps, generally preferred. If, however, despite well-directed efforts, suppuration should occur, so soon as any accumulation of pus can be made out, it should be evacuated.

It is well, in opening and treating mammary abscesses, to observe antiseptic precautions. *James B. Baird.*

PUERPERAL FEVER. Definition.—This malady may be defined as a continued fever following confinement. The opinion of the majority of pathologists of to-day is, that puerperal fever is produced by sepsis. An immense amount of labor is being done at present to elucidate and define the nature of this septic cause.

The type of the disease varies greatly, consequently its manifestations possess a wide range. This range covers, according to recent authors, the following conditions: *puerperal metritis; metro-peritonitis; purulent infection, or pyæmia; puerperal septicæmia; puerperal diphtheria* (Garrigues).

Etiology.—The special sources of sepsis are retained portions of the secundines, the hands of the physician, midwife, or nurse, instruments and sponges, and other puerperal-fever patients.

Among predisposing causes may be enumerated long-continued mental depression, blood-poverty, and an unknown epidemiological influence. The writer inclines to the belief that the accumulation of fæces, with its accompanying ptomaïnes, in the colon, so often found in lying-in women, may contribute to the development of this malady. The blood of puerperal-fever patients is profoundly affected. Women with fæcal accumulations in the colon possess a copric blood, which is, possibly, fertile soil for the puerperal sepsis.

Morbid Anatomy.—The autopsy reveals the almost innumerable lesions following sepsis. When death has resulted in a few hours after the septic invasion, before the coarser pathological changes can have developed, the ravages of the morbid germ can be detected in the "beginning inflammation in most of the tissues, such as cloudy swelling, and in the granular infiltration and disorganization of the cellular elements" (Playfair). A profound alteration in the blood is also found, as a great increase in the white corpuscles, an increase in the fibrin and extractive matters, and a decrease in the red blood-cells. The blood also contains an excess of urea and of carbonic dioxide.

Generally, in post-mortem examinations after every form of puerperal fever, there are found lesions of the genital tract, in the shape of lacerations which present an unhealthy appearance, their edges being œdematous and ragged. The endometrium is commonly found in a gangrenous condition. The solutions of continuity found in the vulva, vagina, and uterus present the sources of entrance of the morbid germ; hence this malady is found more frequently in primiparæ than in multiparæ.

At the vulvar orifice these wounds undergo such a change that they present an appearance of ulceration, denominated "puerperal ulceration."

These ulcerations sometimes extend up the vagina and even into the uterus, are surrounded with much œdematous infiltration, and are named by Virchow "malignant internal puerperal erysipelas."

These extensive ulcerations are denominated, according to their site, "puerperal colpitis" or "puerperal metritis."

The pathological changes seen in the uterine parenchyma, in the veins, lymphatics, and pelvic cellular tissue, are often extreme. Pus is often found in the uterine lymphatics and veins, showing the existence of metro-lymphangitis or metro-phlebitis. The pus is oftenest found at the tubal insertions, and is carried along the lymphatics into the pampiniform plexus of veins, thus explaining the frequency with which para- and peri-metritis complicate metritis.

The peritoneum is nearly always affected. Congested patches only may be noticed. Usually the whole membrane is involved, the intestines being bound down with adhesions, thus forming pockets containing pus, with flaky lymph in greater or less quantities. Pericarditis, pleuritis, and meningitis may be seen also—in short, all the serous membranes may be found in various stages of inflammation. The joints may be invaded by fluid, serous or purulent.

To epitomize: First, in the inflammatory form of puerperal fever will be found lesions confined chiefly to the pelvic tissues and to the peritoneum. Second, in the pyæmic form will be found phlebitis, with metastatic abscesses in any of the organs, as the ovary, liver, lung, kidney, spleen, eye, muscles, and connective tissue. Third, in the septicæmic form lymphangitis is the chief morbid feature of interest.

The pathological changes are the most pronounced in chronic cases.

Symptomatology.—There is a greater latitude in the symptoms of this malady that in those of any other disease.

The only constant symptoms in all forms of puerperal fever are the *facial expression* and the *pulse*. The symptoms most conspicuous in any one form of this disease may be only feebly marked or wholly absent in the other forms. Reflection indicates at once that, the pathological conditions of puerperal fever being so varied, there must necessarily be a great diversity of symptoms manifest in this terrible malady. Hence any description of the symptoms intended to cover all cases must be incomplete. The following may suffice to give a very brief clinical history of the progress of a case of puerperal fever:

The disease is ushered in, within from two to four days after delivery, with a chill—varying anywhere between the two extremes of a succession of slight cold waves, originating apparently in the spinal cord, to a severe prolonged chill lasting an hour or longer. In the majority of cases this chill-invasion is insidious; in some cases it is wholly absent. Following it there is an alarming increase in the pulse-rate—alarming because it is always present in this malady and at once indicates the gravest possibilities. It may vary from 100 to 150 or more beats per minute. Accompanying this rise in the pulse-rate is an elevated temperature, generally to 102°, and, in the severest cases, to even 105° or 106°. The countenance early becomes sallow and sunken, and has a most anxious expression. The skin is hot and dry. The lochia are greatly diminished or wholly suppressed, and the mammary secretion may be arrested. In many cases there is severe general cephalalgia, and oftentimes delirium is early developed. The absence, or a great perversion, of sleep is observed. The tongue is heavily coated early in the disease, and soon becomes dry and rough, and sordes appear on the gums and lips. Vomiting is often present, the ejecta being dark and of a peculiar odor. Tympanites, with much pain and tenderness aggravated by pressure, soon presents itself—although peritonitis, with effusion, may arise without these abdominal symptoms. Diarrhœa is often present, the evacuations being horribly fetid. Jaundice may develop. The breathing is often short and hurried. Pneumonia, pleurisy, or pericarditis occasionally ensues. The urine is generally much diminished, and albuminuria often supervenes. In pyæmic cases, suppuration develops in the joints or in any organ of the body. When fatal, the disease terminates usually within a week. The patient dies from exhaustion.

The foregoing may be regarded as a condensed and, necessarily, an incomplete syllabus of the symptomatology of this disease. It seems expedient to give a more amplified description of symptoms met with in a great many different cases, arranged under the headings of the various systems of the human organism.

The Nervous System.—In patients about to develop puerperal fever will be noticed a condition (properly belonging to the nervous system) of fatigue, as though they had not yet recovered from the shock of labor. Later the characteristic anxious facial expression is always developed. A certain amount of indefinable nervousness and apprehension is nearly always present, and is often accompanied with præcordial distress. The absence of these symptoms is very noticeable in women who have no puerperal troubles. Headache soon develops in the majority of cases. It is *general,* and is not confined to any single region of the head—as the corona, occiput, or temporal region. Sometimes it is very severe; at others it is not complained of greatly.

Later, delirium often arises. At first it is characterized by the patient being dazed for several minutes upon waking, and unable to tell where she is, or to recognize her surroundings or her friends. Some cases present delirium early in the course of the fever, and it grows more and more pronounced until it is continuous. As the patient approaches the fatal issue, the delirium becomes low and muttering. In cases that recover, the cerebral nutrition is often at such a low ebb that the patient is continually possessed of hallucinations of vision and hearing. She sees all sorts of weird objects and sights that have no existence, and hears conversations that do not occur. This is a condition often seen in feeble patients with other diseases. In many fatal cases the intellect is singularly clear till within a few hours of death, when the low, muttering, lethal delirium sets in. Oftentimes the delirium is manifested only at night, alternating with intervals of consciousness. In such cases the contrast of the nurse's night report with that which the physician beholds in his patient in the morning leads him to suspect the nurse's accuracy of observation. Occasionally this intermittent delirium is very severe, bordering on mania.

Subsultus tendinum and carphologia are often developed in the later stages of the disease. The hands and lips may tremble when they touch anything.

There is generally a chilliness preceding the rigor which commonly ushers in puerperal fever. The rigor is often absent, or so slight as to escape observation, or is attributed to some fugitive cause. In other cases the rigor is repeated and very severe, and this is especially so in the pyæmic form. Sometimes rigors, with exacerbations of the general symptoms, are observed on the sixth or seventh day; D'Espinne attributed the occurrence of these to fresh accessions to the systemic infection from putrid pus in the peritoneal cavity.

Pain is generally a marked characteristic of peritonitis, though not an invariable one. It begins in the hypogastrium, and soon invades the entire abdomen. Sometimes the pain is slight. In some cases it is wholly absent, and yet peritonitis progresses to its inflammatory sequences, terminating fatally in the great majority of cases.

The Circulatory System.—The increase in the pulse-rate is always present, from 100 up to 150 and higher, often reaching an uncountable point before the demise. Acceleration of the pulse from transient causes, as the nervous excitement of the advent of the physician, mental annoyance, hot drinks, etc., is to be excluded from the important symptoms. An unaccountable acceleration of the pulse is always alarming in recent puerperal patients. A pulse above 130 beats per minute is always of the gravest import. The arterial tension is always lowered, as is shown by the weak, thread-like pulse. If the pulse-rate diminish, and a corresponding improvement obtain in other respects, it augurs well.

The Respiratory System.—The breathing soon becomes short and hurried. If tympanites develop, the rate of respiration is greatly accelerated. Later, as the heart grows weaker, the patient becomes cyanotic. Toward the last the breath has a heavy, sweetish odor. The respirations may be from 50 to 60 or more per minute. Often pneumonitis, or pleuritis, or pericarditis may develop. In the cases of purulent infection embolic infarctions supervene in the lungs, pleura, or pericardium, often followed by suppurative inflammations terminating in abscesses. In cases of peritonitis, when the tympanites is enormous the breathing is wholly thoracic, the patient lying on her back with her knees drawn up.

The Alimentary System.—The tongue at first presents no distinctive character, but later it becomes furred. Soon thereafter it is covered with a heavy, deep fur—white or brownish. Still later it becomes dry and rough, and is often indented with the teeth. Toward the last the tongue, gums, and lips are covered with sordes.

Thirst is generally great. The more the cutaneous transudation prevails, the greater will be the thirst. Its absence is a favorable symptom.

Vomiting does not often occur early. The ejecta are dark, like coffee-grounds, and are occasionally very offensive. Sometimes they are feculent. It often continues to the end, or it may be present only a short time.

Diarrhœa is of frequent occurrence. Occasionally it is profuse and uncontrollable. In mild cases it is often salutary. When the case is severe, and the diarrhœa increases and becomes more and more offensive, the outlook is gloomy. The more malignant the case, the earlier will the diarrhœa develop.

Tympanites appears betimes. Sometimes it develops within twenty-four hours after the initial chill; at other times it supervenes much later. It may arise from digestive perversion or from peritonitis. Often it is extreme, causing the greatest distress, and persisting to the end. The meteorism is most marked in cases of peritonitis. The muscular coat of the intestine becomes paralyzed and the distention of the intestine is enormous. The patient occupies the dorsal decubitus, and often cannot bear the weight of the bedclothing. Toward the end the distention, with its pain and tenderness, often diminishes, and thus would mislead the physician but for the ominous pulse and facies.

Occasionally constipation exists, and is inordinately rebellious.

The Renal System.—The urine is diminished in quantity, sometimes almost to the point of its total suppression. Its watery element is deflected through the cutaneous and alimentary channels in the forms of sweat and diarrhœa. Consequently it is very dark from concentration, often having the appearance of blood. Albuminuria is often present.

The Cutaneous System.—As a rule the skin is dry and hot, but later in the disease it is bathed in sweat. An occasional case is seen in which sweating is continuous throughout; this Blundell regarded as a distinct variety of puerperal fever, calling it "hidrotid fever." Cases occur in which a rigor, a hot stage, and sweating quickly follow each other; they may at first be regarded as malarial, but as the case progresses they soon declare their malign meaning. Often the sweat possesses a peculiar odor. Toward the close the skin is always cold, damp, and clammy. Now and then a peculiar yellowish discoloration of the skin is observed. Jaundice is occasionally developed. Rarely, transient patches of erythema are seen on various parts of the skin. An eruption of sudamina commonly results from the profuse sweating. Occasionally a scarlatinoid eruption is seen.

General and Special Symptoms.—*The Temperature.*—The temperature is always elevated, and is characterized usually by a morning remission and an evening rise, or exactly the reverse. In mild cases it rises to 102° on the second or third day. The sooner after delivery that it is observed, the more alarming does it become. The fugitive rise of temperature from mammary and alimentary irritation will be borne in mind while investigating the possible advent of puerperal fever. In fulminant cases the temperature may not rise above 100°, while in comparatively mild cases it may rise to 104°, or even higher. In large remissions of temperature, not in

collapse, the outlook is favorable. In severe cases the temperature rises at once to 104°, or even to 106°, and it is subject to sudden remissions and exacerbations.

The Lochia.—The discharge is often diminished, and in a certain proportion of cases is wholly suppressed. When not entirely suppressed it becomes characteristically fetid. There are cases in which it is more than usually abundant.

The Mammary Secretion.—Rarely, the flow of milk is abnormally large. Diminution, even to the disappearance, of this secretion is the rule. The breasts often become hard and painful.

The Generative Organs.—Uterine tenderness on pressure, after the second day increasing very markedly, indicates the development of the endometritis which precedes general metritis and systemic infection. The fundus can easily be felt through the hypogastrium, and when its tenderness is physiological—*i.e.*, when it arises from massage to facilitate placental expulsion—Priessnitz compresses will cause its disappearance.

After-pains continuing or arising after the third day in multiparæ are suspicious of sepsis. When they are well marked in primiparæ they show incomplete uterine contractions, which may be followed by infection or by hæmorrhages.

The vulva may become œdematous, and be the seat of diphtheritic ulcers.

Localized Inflammations and Suppurations develop in the pyæmic forms. They may occur in any joint, and are always accompanied by the usual subjective and objective symptoms characterizing such conditions. Large caverns of pus may develop in the muscles and in the connective tissues. Any organ may be the seat of abscess-development.

Prognosis.—Until the patient is manifestly improving, all attempts at a reliable prognosis are extremely problematical. When the disease begins early—within the first thirty-six or forty-eight hours—the case will generally be a severe one. When the chill is repeated at intervals, being preceded by improvement, the danger lies in the possibility of the repeated infections fatally exhausting the patient. The general condition of the patient signifies much—the better it is at the time of the attack the better are the chances of recovery. In pyæmic cases the prognosis is invariably gloomy. Para- or peri-metritis followed by abscesses may result in chronic invalidism, lasting months or years.

Treatment.—*Prophylactic.*—This is of prime importance. Mindful of the channels of infection, the physician is enabled to avoid sepsis in the majority of cases. Before touching the patient the hands should be thoroughly disinfected by rinsing in a carbolized solution of the strength of 1 to 20, or by anointing with carbolized vaseline—1 to 20—after they have been well washed in hot water and castile-soap, particular attention being paid to the finger-nails. All instruments and sponges used in the genital tract should be carefully carbolized. The careful and complete delivery of the secundines is absolutely indispensable.

When lacerations exist, they should be carefully cleansed by irrigation with a 1 to 40 solution of carbolic acid and dusted over with iodoform.

General Treatment.—The source of infection should be determined if possible, in the hope of arresting further accessions to the sepsis. In most cases it lies in the vulva and vagina. When the attendant is convinced that it arises from the uterus, the intra-uterine douche of an antiseptic solution should be promptly used. Weak solutions of carbolic acid, corrosive sublimate, iodine, or Condy's fluid, can be used through a double-current catheter every eight, twelve, or twenty-four hours. Corrosive sublimate is much lauded for its germicidal properties, and can be used in the 1 to 3,000 solution. It is dangerous, cases being recorded in which death through toxic nephritis has followed its use. After the intra-uterine douche, a bacillus containing 50 to 100 grains of iodoform should be introduced into the uterine cavity. These local applications should be used so long as they are of advantage. After the use of the intra-uterine antiseptic douche, the temperature usually falls—in some cases from three to six degrees—and often this decrease in temperature is final. More frequently, however, it is followed by another rise, due to new absorption, and the repetition of the douche is followed by another defervescence. Thus, cases will be found in which the repeated fall of temperature and its later rise after the douche will extend over many consecutive days. Local treatment is more effective and direct than general medication.

Pain.—For this symptom, opium or its derivatives can be used. It must be given in quantities sufficient to allay suffering, subdue restlessness, and induce sleep. Laudanum in poultices over the abdomen often proves grateful. When opium cannot be borne, chloral hydrate or cannabis indica may be used. Two parts of extract of belladonna and one part of glycerine, thickly spread over the whole abdomen, often relieves the great tenderness found present with extreme intestinal distention. In peritonitis hot fomentations are often singularly grateful. Turpentine stupes are also of great value. Collodion over the whole abdomen is decidedly useful in alleviating the pain of this complication.

Fever.—For this manifestation, quinine is of great service. It should be given fearlessly and continuously—say, in ten-grain doses every four or six hours, until defervescence sets in; when head-symptoms follow its use, hydrobromic acid often allays them. The baleful effects of quinine on the stomach must be borne in mind. Warburg's tincture has been recommended for the purpose of lowering the temperature. Antipyrin has been recommended likewise. The theoretical objection to it—its cardiac depressing influence—deters many physicians from using it. Veratrum viride, in five-drop doses of the tincture hourly until the pulse falls below 100, afterward two or three drops every second hour to hold the pulse steadily below 100, is greatly praised by Fordyce Barker. Aconite may be similarly used. Both of these remedies are contra-indicated when the vital powers are much prostrated, as is indicated by a weak, thready pulse and cold extremities. Cold sponging in sthenic cases has its advantages.

Vomiting is often uncontrollable. Champagne or raw brandy will sometimes arrest it. Sulphate of magnesia, in thirty- or forty-grain doses in tepid water every hour, or every second hour, till the bowels move, often arrests vomiting. Three to five grains of calomel every three or four hours to purgation will sometimes accomplish the same end. The tendency to diarrhœa in this disease is not to be forgotten, and its artificial production must be undertaken with caution. In persistent vomiting rectal alimentation can be resorted to.

Tympanites may often be relieved by the use of the rectal tube every three or four hours. It usually manifests itself first in the transverse colon, and can be detected by a bulging at the scrobiculum cordis. The use of sulphate of magnesia or of calomel to catharsis often relieves distention. Placing the patient on her face, with her thighs drawn up under her abdomen, often causes enormous expulsions of gas with great relief (Parkes). Turpentine internally is sometimes of marked advantage.

Diarrhœa often occurs in acute cases toward the close of the scene, and can be restrained by no remedy. In chronic cases it is frequently a prominent symptom, and may be checked by the use of the tincture of the perchloride of iron in twenty- or thirty-minim doses.

Food and Stimulants are to be used frequently and in small quantities. Concentrated beef-tea, milk, eggs, brandy, and champagne are the main stays in supporting the patient until the effects of the poison are worn off. The most abundant supply of fresh air compatible with safety should be secured. *James H. Etheridge.*

PULASKI ALUM SPRINGS. *Location*, Pulaski County, Va.

Post-office, Dublin, Pulaski County, Va.

Access.—By the Norfolk & Western Railroad to Dublin; thence by stage to the springs, twelve miles.

ANALYSES.—These are, according to Walton, very similar to the Rockbridge Alum Springs of Virginia.

The springs are located at the base of Walker's Mountain, on the bank of a creek, in the extreme southwestern part of Virginia, amid the picturesque scenery of that region. There is a hotel at the springs.

G. B. F.

PULEX PENETRANS, chigoe, chiggre, jigger, sand flea, rhynchoprion penetrans, is a minute parasite abounding in the West Indies and tropical regions of the Eastern and Western continents. The female alone attacks man, and does so for the purpose of depositing her eggs. She penetrates the thin skin between the toes or about the toe-nails, and then swells up to the size of a pea, forming a bag of eggs; this causes much irritation, which often results in suppuration, followed by open ulcers. This is generally regarded as a true flea; it lives in dry, sandy places, and multiplies prodigiously.

When the chigoe is recognized under the skin, it should be carefully removed, or if suppuration has already occurred, the parts should be washed with solutions of carbolic acid, carbolized oil, etc.

Charles E. Hackley.

PÜLLNA is a village in Bohemia, in which are several springs of a bitter water, well known and frequently employed in this country as a mild and efficacious laxative. The water resembles closely that of Hunyadi Janos, but is milder and less certain in its action.

The composition of the water varies within certain limits, but not sufficiently to be a matter of any particular importance. The following is the analysis given in the U. S. Dispensatory (15th edition, 1883), after Struve. One pint contains:

	Grains.
Magnesium carbonate	6.406
Calcium carbonate	0.770
Magnesium chloride	19.666
Potassium sulphate	4.800
Sodium sulphate	123.800
Magnesium sulphate	93.086
Calcium sulphate	2.600
Calcium phosphate	0.003
Silica	0.176
Total	251.307

The dose of Püllna water is one or two glasses in the morning as a laxative; for its so-called alterative effects it may be taken in ounce or half-ounce doses, several times a day. The water is exported exclusively, and there are no accommodations for visitors at Püllna. *T. L. S.*

PULSATILLA, U. S. Ph. (*Anémone Pulsatille* or *Coquelourd*, Codex Med.). "The herb of *Anemone pulsatilla* Linn., and *Anemone pratensis* Linn., and of *Anemone patens* Linn., *var. Nuttalliana* Gray, Order *Ranunculaceæ*, collected soon after flowering" (U. S. Ph.). The Anemones are perennial herbs, with flowers having the general structure of buttercups, but without petals, the place of the corolla being taken by a showy calyx of large colored sepals (purple, blue, white, etc.), while the calyx is simulated in some instances by a conspicuous involucre. Stamens numerous, the outer sterile; pistils also many, small, simple, covering the convex receptacle, and ripening into one-seeded achenes, styles persistent, often long and plumose. *A. pulsatilla* is a low hairy plant, with a short, thick stem, and a cluster of doubly pinnate and dissected radical, hairy leaves. Flowers solitary on hairy scapes, two or three centimetres across, with the involucre some distance below the calyx. It is a native of England and Northern Europe. *A. pratensis* has the involucre near the calyx, and a less open flower; it grows in the southern part of Europe. *A. Nuttalliana* is a native of North America.

The leaves of Pulsatilla have a very sharp, stinging taste, like that of the buttercups, and but little odor; they grow insipid by age, and should not be kept more than one year.

COMPOSITION.—The Anemones, in common with buttercups and probably some other *Ranunculaceæ*, contain a very pungent, volatile, *oil-like principle*, which can be separated by distillation with water. Upon long standing it separates two solid substances, *anemonin* and *anemonic acid*. The former is a colorless, crystalline, neutral substance of but little taste when cold, but intensely pungent when melted. It is but slightly soluble in cold alcohol, ether, or water; more so in those liquids when hot. This is the active principle. *Anemonic acid* is a white, amorphous, insoluble substance, of neither odor, taste, nor medicinal properties.

FIG. 3130.—Anemone Pulsatilla. (Baillon.)

ACTION AND USE.—Pulsatilla is an old remedy, with a good many reputed empirical powers. It has had a reputation in chronic eruptions, syphilis, "ophthalmia," amaurosis, nasal and bronchial catarrh, etc. It is now sometimes given in dysmenorrhœa, whooping-cough, asthma, etc., with supposed advantage. It is extensively used in homœopathic practice. Anemonin is an active poison, reducing the heart-beats in number and strength, and reducing the number of respirations. Collapse, paralysis, stupor, and convulsions have been observed after its administration.

Dose, of Pulsatilla one or two decigrams (gr. ij. ad iij.); of Anemonin, one or two centigrams (gr. $\frac{1}{6}$ to $\frac{1}{3}$).

ALLIED PLANTS.—A number of Anemones are favorites in the flower-garden, others are well known and pretty wild flowers. *A. nemorosa*, the wind-flower, is reputed to have properties similar to the above. See ACONITE for the order.

ALLIED DRUGS.—There is a family resemblance in the

actions of a good many of the *Ranunculaceæ*. *Anemone, Ranunculus, Adonis, Clematis, Delphinum*, etc.; *Symplocarpus* (Skunk Cabbage), and *Arisæma* (Indian Turnip) have a similar acrid, benumbing principle.

W. P. Bolles.

PULSE, ARTERIAL. With each systole, the left ventricle of the heart propels into the already full aortic system an additional volume of blood. The time occupied by the influx of this volume of blood into the aorta is the period from the opening of the semilunar valves until the beginning of relaxation of the ventricle. The same volume of blood escapes from the arterial system through the capillaries in the time occupied by one entire cardiac cycle, of which the period of influx is only a part. Hence only a part of the volume of blood thrown into the aorta escapes during the time of its influx; for the remainder room is made for a while by a dilatation of the (yielding) arteries. This dilatation takes place first in the root of the aorta, is quickly propagated along the arterial tree in the form of a wave, and is immediately followed at each point by a contraction of the (elastic) arterial wall. This alternation of dilatation and contraction of the arterial tube is called the pulse.

The *velocity of transmission of the pulse-wave* differs not only in different vessels, but in the same vessel under different conditions. For peripheric arteries, the average rate was found by Weber, 9.240 metres per second; Landois determined it 6.431 m. for the lower extremities, and 5.772 m. for the upper; Grunmach 6.6 m. in the direction of the carotids, 9 m. in the upper extremities, 11 m. in the lower; Moens found an average rate of 8 to 8.5 m.; Grashey, 8.53 m. "The velocity of the pulse-wave normal to the individual is closely preserved under ordinary physiological variations of the circulation," and the pulse-rate has no notable influence over it (Keyt[1]). It is much slower in young children than in adults, and increases with increase of age (*Id.*) Rise of blood-pressure increases the rate of transmission, and *vice versa*. Morbid processes which affect the diameter, thickness, and elasticity of the arteries, affect also the velocity of the pulse-wave, according to known laws.* Grunmach[3] saw it diminish in most cases of valvular disease of the heart, according to the degree in which the functional power of the heart was lowered. Lead-poisoning, digitalis, and caffeine increased it parallel with the increased arterial tension; chloroform, chloral, and morphine diminished it.

The interval between the heart-beat and the radial pulse is commonly .15 to .2 second; it is altered in some diseases, notably lengthened in mitral, shortened in aortic insufficiency. In the radial artery, the pulse arrives about one-fifteenth to one-tenth second later than in the carotid; Czermak states the difference as .094 second. Landois found the difference in time between femoral and dorsalis pedis, .154 second; between axillary and radial, .087 second; between axillary and dorsalis pedis, .212 second. Keyt[4] gives the mean time-difference between carotid and radial as .0714 to .0888; between carotid and femoral, .050 to .0909; between carotid and posterior tibial behind the malleolus, .125 to .166 second. Moens observed, for the latter, .167 to .178 second.

The pulse is examined by means of palpation, inspection, auscultation, and by the graphic method (sphygmography). Apart from murmurs produced in the arteries by disease of the walls, and from sounds and murmurs transmitted from the heart (which are not within the province of this article), there may be heard in some arteries sounds and murmurs produced by the pulse itself. Wolff,[5] who appears to have been the most expert auscultator of the pulse, recommending practice on the brachial artery in the bend of the elbow, says: "With the common normal cubital pulse of persons of middle age [in lean individuals, especially convalescents], there are heard three sound-like murmurs, coalescing when the stethoscope is lightly applied, but more or less distinct, and therefore shorter, upon closer approximation to the artery; their strength and *tempo* correspond to the size and sequence in time of the three pulse-strokes and the three large elevations of the curve." In the pulse of the aged, the first and second murmurs only are heard; in the dicrotic pulse the first and third are heard distinctly. The radial pulse has likewise been heard by Wolff, but other auscultators have been less successful. Thus far, the auscultation of these murmurs has not added to our knowledge of the pulse.

Inspection of the skin over superficial arteries sometimes reveals the existence of visible pulsation in parts where normally no pulse is seen. During excited action of the heart, in cardiac hypertrophy, in vaso-dilatation of a part, the pulse of some arteries usually concealed becomes visible, as in the well-known throbbing of the carotids and temporals in congestion to the head, the phenomenon of epigastric pulsation, etc. Bettelheim[6] calls attention to visible pulsation of the brachial artery as frequently of diagnostic value. Under normal circumstances it is often, but not always, seen in old people, only now and then (feebly) in emaciated persons, and after violent exercise of the muscles of the arm; when present under other conditions it indicates aortic insufficiency, arterio-sclerosis, or hypertrophy of the heart.

PALPATION.—The act of feeling the pulse was in danger of being lost in the present century, when improvements in physical exploration in other directions—percussion, auscultation, thermometry, etc.—diverted the attention of the physician from the pulse, and the traditional habit of placing the fingers upon the patient's wrist began to have little result beyond counting the number of pulsations in a minute. The recent application of accurate experimental methods to the investigation of the pulse has been the means of once more educating the touch to a better appreciation of the movements of the artery, to a nearer approach to the *tactus eruditus* of old.

Palpation of the pulse is performed by placing the tips of at least two, better three, fingers close together in a line upon the arterial tube, and with a certain practised elasticity of touch, the fingers following or yielding to the movements of the arterial wall. The (radial) artery should, moreover, be put in a favorable position by relaxing the tissues about it, holding the forearm midway between pronation and supination, both hand and forearm being gently flexed. By this means are detected differences as to (1) frequency and rhythm; (2) degree of resistance to pressure, compressibility; (3) magnitude; (4) celerity; and (5) secondary waves.

Pulse-rate.—The frequency of the pulse depends solely upon the movements of the heart, each pulse-beat representing a contraction of the left ventricle. The normal pulse of the adult male varies from 60 to 80 beats in the minute; the statement that the mean of numerous observations in many individuals lies between 71 and 72 is of no value, because the range of individual variations is very great. The range of the pulse-rate in females is even greater, not a few having an average pulse of more than 80 beats, and some of less than 60; the majority show a higher frequency than males. In children the pulse is more frequent: At birth, 128 to 144; in the first year of life, 120 to 130; at the age of ten years, 90. In old age the pulse is usually more frequent than 72, but often also much rarer, between 50 and 60. The pulse-

* The rate of transmission of waves in elastic tubes can be calculated by the formula of Moens,[2] $Vp = 0.9\sqrt{\frac{g\,E\,a}{\Delta\,d}}$, in which Vp stands for the distance which the wave travels in one second, expressed in centimetres; g for the acceleration of gravity = 980.88 centimetres; E for the coefficient of elasticity of the tube (in grammes per square centimetre); a for the thickness of the tube in centimetres; d for the diameter of the tube in centimetres; Δ for the specific gravity of the liquid. Hence the velocity of transmission varies inversely as the square root of the specific gravity of the liquid; directly as the square root of the thickness and inversely as the square root of the diameter of the tube; and directly as the square root of the coefficient of elasticity of the wall. The first-named factor, Δ, can be disregarded in the case of the arterial pulse, since the specific gravity of the blood varies too little to affect perceptibly the rate of transmission. Keyt (l. c.) has arrived at similar results, and demonstrated some of them in cases of disease.

rate is higher in short than in tall persons.* Habitual pulse-rates below 56 and as low as 46 have been observed in healthy adults, but they are rare exceptions.

The pulse-rate varies somewhat with the time of day, independently of meals and movements, diminishing in the forenoon, rising in the afternoon, sinking during the night, and rising in the morning. The first maximum is reached between 8 and 11 A.M., the second between 6 and 8 P.M.

The frequency of the pulse is increased by the activity of the working organs: by muscular labor, by digestion (increased glandular labor), by psychical processes (emotions, pain, intellectual labor). Exposure to heat, and elevation of the body-temperature, raise the pulse-rate. Position (in accordance with the muscular labor involved) affects the pulse-rate, which is higher standing than sitting, higher sitting than lying. Guy[7] found the averages in adult males standing, 79; sitting, 70; lying, 67; with remote extremes, and the differences increasing with the frequency of the pulse. The differences are less marked in females, and in early youth. Graves states that in hypertrophy of the heart these differences disappear, and the same has been said[8] of pregnancy.†

Rise of arterial blood-pressure diminishes the pulse-rate, and, *vice versa*, a fall of blood-pressure increases the frequency of the pulse (Foster,[9] Mahomed[10]).‡

Tarchanoff recently studied and reported[29] the case of a young man who had the power of voluntarily accelerating the action of his heart, probably the only authenticated exception to the rule that the pulse-rate is not subject to the will.

Variations in rhythm are more accurately observed by instrumental means than by palpation, and will be described later.

Compressibility.—The degree of resistance to the finger depends partly upon the degree of elasticity of the artery, becoming greater with increasing rigidity of the tube, as in the aged; partly upon the blood-pressure. In order to estimate the mean blood-pressure (not only during, but also in the intervals between the beats) it is necessary (1) to place the (three) fingers lightly upon the vessel and with them move the integument over it in a transverse direction, rolling, as it were, the artery under the fingers (observation of the size of the artery apart from its distention by the pulse is a very important and much neglected function of palpation; a pulse of high tension may be witnessed in a contracted artery as well as in a large artery), and (2) with the finger nearer the heart to compress the artery until the pulse is no longer felt by the distal fingers. When the mean blood-pressure is high, the artery is felt distinctly as a cord; deeper pressure does not readily suppress the pulse, but makes the impact of the wave more distinct. In low tension, the artery is flattened by moderate pressure and the pulse is easily suppressed. The exact estimation of the degree of resistance by palpation is difficult and requires great attention, chiefly because the finger takes cognizance, not of the compressibility of the artery alone but at the same time of the rigidity of the vessel, its size, and the amplitude of the pulse-wave. More accurate results are obtained by instruments of precision, as Waldenburg's *Pulsuhr*,[11] and v. Basch's *Sphygmomanometer*;[12] indirectly, the sphygmograph also indicates the tension of the arterial wall.

The other qualities of the pulse which can be perceived by the finger are better studied with the help of the sphygmograph, whose lever magnifies the movements of the

scription of the instruments and their use, consult article Sphygmograph.)

FIG. 3134.—Normal Tracing by Burdon-Sanderson's Modification of Marey's Sphygmograph. Pulse-rate, 72. The above, and subsequent tracings illustrating this article, unless otherwise specified, are reproductions of originals in my possession by photographic means only, without drawing or retouching. Those by the Burdon-Sanderson instrument (which has a rapid movement and magnifies more highly than the other instruments used) were taken and kindly furnished by Dr. William Townsend Porter, late Senior Assistant to the St. Louis City Hospital. When the artery is not designated, the tracing is to be understood as that of the radial artery.

SPHYGMOGRAPHY.—*The Normal Pulse-curve.*—As the artery dilates, the lever of the sphygmograph rises rapidly and marks upon the recording surface a *line of ascent* or *up-stroke* (Fig. 3135, *ab*), which is very steep, almost vertical; at the end of the dilatation the lever falls, marking a *line of descent* or *down-stroke*, *ba'*, which makes a well-defined acute angle, *apex*, *b*, with the line of ascent. This line of descent is sloping, and is interrupted by several secondary elevations. The most important of these, rarely absent, divides the line of descent into two nearly equal parts, the upper half terminating in a more or less well-marked depression, the *diastolic notch* of Burdon-Sanderson (Mahomed's aortic notch, Wolff's *grosse Incisur*), *e*, which is succeeded by a new rise of the lever marking the *dicrotic elevation*, *f*. The line of descent is further interrupted by minor elevations, the first of which precedes the dicrotic elevation, hence *predicrotic wave*, *d*, and is discernible in every well-written normal curve, while those which succeed the dicrotic wave are commonly faint or may be wanting.

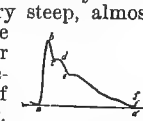

FIG. 3135.—Normal. Pulse-rate, 53. (Pond's.)

These divisions of the tracing express the events occurring in the movement of the arterial wall. The beginning (*basal point*) of the curve marks the opening of the aortic valves, the line of ascent expresses the influx of blood into the arterial tube. This line is not perfectly straight; the lever rises at first with increasing velocity and arrives at the apex with lessening velocity, tracing a line curved like a very long-drawn italic *f*. In some pathological curves the up-stroke is broken by one or more secondary (*anacrotic*, Landois) elevations; but this never happens in the normal curve. When the moment of greatest distention is reached the lever descends at once; the apex is a clean-cut angle. The descent, more gradual than the ascent, is due, of course, to the steady outflow of blood toward the capillaries. For a short time the

* So close is the relation of the average frequency of the pulse to the body-height, that various observers have been able to propose formulas for computing the pulse-rate from the height. According to Vierordt, the duration of each pulse increases by about .03 second with every increase of height of 1 decimetre. Rameaux, by theoretical reasoning, deduced the formula $n' = n\sqrt{\frac{d}{d'}}$ (n, n' denoting the pulse-frequencies, d, d' the body-lengths), which for adults gives computed pulse-rates agreeing very closely with the rates observed (Landois). Volkmann's formula, written in the same term is $\frac{n}{n'} = \frac{d'^{\frac{5}{9}}}{d^{\frac{5}{9}}}$

† Contrary to Hohl, who gave the pulse-rate of pregnant women standing, 94; sitting, 83; lying, 77 (Die geburtshülfliche Exploration, 1835).

‡ Landois makes the reverse statement (Lehrb. d. Physiologie, 2. Aufl., 1881, p. 142).

ventricle is held in systole ; at the end of this period, the ventricles relaxing, a small reflux of blood closes the aortic valves with a short snap, which starts a small positive wave, expressed in curves obtained from the largest arteries (carotid, axillary, femoral) by a small elevation below the apex. This wave is lost before it reaches the radial artery. In the radial trace there occurs, nevertheless, a predicrotic wave which is commonly explained * as the first, and therefore largest, of a series of wavelets due to elastic oscillations of the tense arterial wall (*Elasticitätselevationen*, Landois).

The dicrotic wave owes its origin to a different cause. The cardiac systole communicates a progressive movement to the blood in the aorta, which, in virtue of inertia, continues a short time after the closure of the aortic valves; a rapid lowering of the blood-pressure in the root of the aorta results. The contraction of the arterial wall, therefore, drives the blood, not only in the direction of the capillaries, but also, for an instant, toward this point of less pressure : a momentary reflux of blood upon the (closed) aortic valves ensues, which, rebounding, starts a positive wave (of recoil, *Rückstosswelle*, Landois ; *Schliessungswelle*, wave of closure, Moens) that is expressed in the pulse-curve by the dicrotic wave. If time be given before another cardiac systole repeats the cycle of events, the second half of the down-stroke may show a (smaller) second wave of recoil, as well as some elastic elevations. The elevations occurring in the line of descent are known as *catacrotic* elevations (Landois).

In the normal radial curve are always seen at least three distinct elevations : the primary wave (percussion-wave, Mahomed †) or apex, the predicrotic (tidal, Mahomed), and the dicrotic wave ; and, hence, disregarding the lesser oscillations which may follow, the normal curve is spoken of as " tricrotic." The relative size and position of these waves depend upon the conditions of the circulation, viz., the force of the heart's contraction and the amount of blood thrown into the artery, the tension and elasticity of the arterial wall, and the freedom of the distal outflow. According as these conditions vary the form of the curve is modified.

Amplitude.—The excursions of the lever, *i.e.*, the dilatation of the artery, may be greater or less, depending (1) upon the volume of blood propelled by each systole, and (2) upon the ratio of propelling force to resistance of the arterial wall. (The magnitude of the pulse-curve has, of course, no direct relation to the size of the vessel, which may be small [contracted] or large [expanded] and which must be *felt*, for the sphygmograph gives no indication of its diameter ; it must also be remembered that a superficial artery gives an ampler tracing than one covered by thicker layers of tissue.) A well-filled ventricle is indicated by great amplitude of curve ; but if the ventricle pumps only a small quantity of blood at each contraction, a low curve results. When the arterial tension is low, and the outflow toward the capillaries free, the lever falls deeply during the cardiac diastole, and a large curve results ; but when the outflow is obstructed, and the artery is already full and tense at the beginning of the systole, the curve *c. p.* is small. Thus we see a *large pulse* (*pulsus magnus*) in hypertrophy of the heart, in acute fevers (with low blood-pressure) ; a *small pulse* (*p. parvus*) in feeble action of the heart, in pulmonary obstruction, and in mitral insufficiency (imperfect filling of the left ventricle), and likewise in cases of high tension not overbalanced by increased power of the heart.

* Maurer [13] thinks that the predicrotic wave is caused by the closure of the aortic valves in all arterial pulses : that only the small wavelets sometimes added, most often between the predicrotic and the dicrotic wave, are elastic oscillations. I have followed the widely accepted interpretation of Landois without intention to decide this point.

† Mahomed conceived that the lever was thrown violently upward by the suddenness—" percussion "—of the systole ; that without this percussion the true apex of the curve would be reached only in the predicrotic elevation, which he therefore termed the tidal wave. This view is not supported by the measurements. A true percussion-stroke is but rarely seen, as in the radial curve in cardiac hypertrophy ; it is well marked in the aortic curves, Figs. 3149 and 3150, where the true apex can be readily distinguished, soon followed by the wave caused by the closing of the aortic valves. The use of Mahomed's terminology has therefore been avoided in the present article.

The height of the curve alone does not indicate (as is frequently stated) the volume of blood propelled at each systole ; this is more properly measured by the area enclosed between the curve and the base-line. A yielding artery (as in fever) is easily dilated, and a curve of greater height results than the same volume of blood produces in a tense or rigid artery. Increasing volume of blood will increase the height of the curve only so long as the force is great enough to propel it with such velocity as to overcome the increasing elastic resistance of the artery.[14] When, however, the arterial tension rises considerably, as by contraction of the minute arteries, the height of the curve no longer increases, the predicrotic wave is near the apex, the descent is delayed, and the dicrotic elevation is higher above the base-line ; *i.e.*, the pulse becomes *tardus* (see below) and the area of the curve is increased, though not its height.*

Fig. 3136.—(Pond's.)*

Celerity.—The rise of the lever may be more or less nearly vertical ; *i.e.*, the time occupied by the dilatation of the artery may be less or greater. It is very brief when the ventricle contracts with energy against a yielding artery ; the dilatation is slower when the heart is weak, or when the resistance in its front is increased by high blood-pressure, or by rigidity of the artery either in its entire course or at some point between the heart and the vessel under examination. In the former case, the up-stroke is very steep, and in a large pulse almost vertical, the apex very acute, and the first portion of the descent also steep ; the artery is quickly distended, and quickly emptied ; hence, the pulse is designated as *p. celer*, the *quick* or *short pulse*. When, on the other hand, the artery is tense or rigid, and does not yield readily, or when the force of the ventricle is small compared to the resistance in front, the pulse appears labored, the line of ascent is more slanting, the artery remains dilated for a time, because its recoil is likewise slow, the apex is blunted, the space between the lines of ascent and descent is widened, the first portion of the descent more gradual. This form of curve pictures the *p. tardus* of the older writers, the *slow* or *long pulse*.† Figs. 3160, 3162, 3177 to 3179, are examples of *p. celer ;* Figs. 3155 to 3157, 3181 to 3184, of *p. tardus*. In some soft pulses the ascent alone is slow, while the descent is rapid, as in Fig. 3137, B.

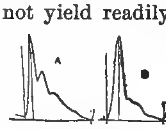

Fig. 3137.—A, pulse-rate, 68 ; duration of pulse, .867 sec. ; of ascent, .102 sec. B, pulse-rate, 80 ; duration of pulse, .752 sec. ; of ascent, .159 sec.

In judging of the steepness of the up-stroke (or down-stroke) the height of the curve must be taken into account ; with the same duration of the period of distention, the ascent must be more nearly vertical in a high curve than in a low curve, as is obvious from the diagram, Fig. 3138. The real criterion is the distance, in time, between the basal point and the apex ; see remarks on measuring the curves, below.

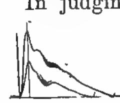

Fig. 3138.

The *Secondary Waves* in the down-stroke (catacrotic elevations) are subject to variations, both in their position and in their size. The conditions which influence them have been investigated by Marey, Landois, and many others. It has been shown that the *dicrotic wave*, in common with other waves, loses in distinctness with the distance from the heart of the artery examined, and

* In Fig. 3136, the area of curve A = 26.36 sq. mm., while the area of the higher curve B = only 19.97 sq. mm. ; the distention of the artery was greater in B, but it lasted longer in A. The area of C = 15.33 sq. mm., while the almost equally high curve D has an area of only 10.55 sq. mm.

† The classical terms, " quick " and " slow " pulse, are nowadays applied so universally, though illogically, to the frequency of the heart's beat, in place of the correct terms " frequent " and " rare," that Burdon-Sanderson proposes the words " short " and " long " as the English equivalents of *celer* and *tardus*.[16] Fig. 3137 shows two pulses of about equal amplitude, of which the rarer, A, is quicker (more *celer*) than B, the more frequent one.

that its distance from the primary wave (apex) is greater in the remote arteries than in those near the heart (because low waves are transmitted with less velocity than higher waves, Moens[16]). In the same locality the dicrotic wave is increased (1) by a short and energetic systole, (2) by diminished arterial tension, and (3) the wave is delayed by low tension (Moens[17]).

The development of *elastic elevations* or oscillations of the arterial tube is favored (1) by high tension, and (2) by perfect elasticity of the artery. Elastic waves are diminished or prevented (1) by low tension, and (2) by loss of elasticity in the vessel through disease of its walls, as in atheroma. Hence, in a vessel of normal elasticity, the size and number of the elastic elevations depend on the degree of tension of the arterial wall.

Tension.—From these propositions it follows that the character of the secondary waves is influenced largely by

FIG. 3139.—Normal Pulse of High Tension, 54. (Pond's.)

the blood-pressure. While it is not the function of the sphygmograph to measure, in any direct sense, the blood-pressure, the recorded curve gives indication of the degree of tension in the artery. A pulse-curve of high tension—the *hard pulse, p. durus* (Figs. 3139 and 3140)—is characterized chiefly by (1) early, distinct, and perhaps

FIG. 3140.—Normal Pulse of High Tension, 70. (Marey's.)

numerous elastic elevations, the predicrotic wave especially is well developed and near the apex, the descent of the lever appears delayed; (2) the dicrotic wave is small in proportion to the amplitude of the tracing; (3) the end of the first part of the down-stroke (the diastolic notch, *e*) is high above the base-line. In some strictly normal pulses of relatively high ("good") tension, the down-stroke forms an almost uninterrupted straight line from the apex *b* to the basal point of the next curve, *a′*, as in Fig. 3158. (Compare also Figs. 3144, 3155 to 3157, 3171 to 3173.)

In a curve of low tension—the *soft pulse, p. mollis* (Fig. 3141)—on the other hand, (1) the elastic elevations are small or absent, the predicrotic wave, if preserved, is comparatively low down in the tracing and small; (2) the dicrotic wave is likewise delayed, but well devel-

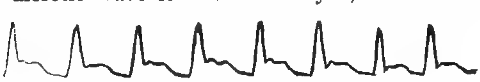

FIG. 3141.—Normal Pulse of Low Tension, 73. (Pond's.)

oped; (3) the first part of the down-stroke makes a steep descent, and forms a smaller angle with the second portion, thus _, and the diastolic notch is near the base-line. Very frequently these modifications coincide with the *p. tardus* and *p. celer* respectively, so that commonly a pulse of high tension is *tardus et durus*, the pulse of low tension *celer et mollis*. (Compare also Figs. 3147, and 3161 to 3170.)

Still further modifications are introduced into the form of the curve by the frequency of the beat. The period of dilatation of the artery, subject to the variations already spoken of (*vide* Celerity), is not influenced materially by the mere frequency of the beat; the period of descent bears no definite ratio to the time occupied by the ascent. A frequent pulse is commonly also a *p. celer*, but a rare pulse may also be *celer*. But when the ventricular systoles follow each other rapidly, the ventricle has not time to fill with the same amount of blood as when they occur at longer intervals; hence the amplitude of the curve is lessened as the pulse becomes more frequent. Moreover, in the frequent pulse the line of descent is cut off sooner by the rising wave of the succeeding beat; hence, while the period of ascent remains nearly the same, the period of descent is abbreviated; the shortening of the curve falls mainly upon the descent. Usually the rise in frequency coincides with a fall in blood-pressure, and *vice versa*, which is likewise expressed in the curve.

Measuring the Curves.—It is difficult for the beginner to estimate the described variations in the curve at sight; this art can be best acquired by practice in the actual measurement of tracings.

Curves of the same pulsation, drawn upon recording surfaces moving at different rates, assume great differences of aspect, while yet they record the same facts. This explains one of the difficulties in comparing tracings by different instruments. Curve A, in Fig. 3142, when traced on a plate moving with twice the velocity, assumes the shape of B; on a plate moving with half the velocity, the shape of C.

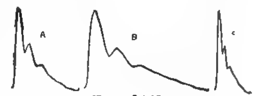

FIG. 3142.

The distance in time between two events of the pulse-movement can be measured on an abscissa parallel to the direction of movement of the recording surface—ordinarily parallel to the base-line of the curves—by means of ordinates drawn through the salient points of the curve. The direction of the ordinates is indicated by (parallel to) the directrix, "signal line," or "guiding line"—a line usually drawn at the beginning of a tracing by the style moving while the recording surface is still at rest (G *a*, Fig. 3143). This, in curves drawn by instru-

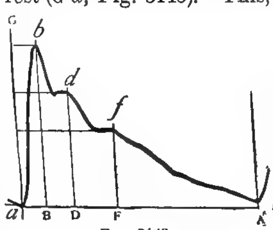

FIG. 3143.

FIG. 3147.

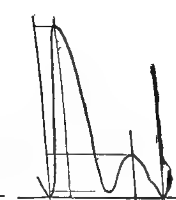

FIG. 3148.

FIGS. 3143, 3144, 3145 (Pond's); FIGS. 3146, 3147, 3148 (Marey's).—All magnified × 2. These curves were magnified (× 8) by the magic lantern, the abscissas and ordinates added, and the drawings reduced by photography (÷ 4).

ments the marker of which moves in a straight line (at right angles to the movement of the recording surface, as in Landois's angiograph, in Pond's and Dudgeon's sphygmographs) is itself a straight line, and vertical to the abscissa if the movement of the marker is exactly at right angles to the base-line, which is not always the case (*cf.* Figs. 3143 to 3145). In curves drawn by a lever that moves around a centre and in a plane parallel to the recording slide (as in Marey's sphygmographs, and in some of the tambour instruments, in Keyt's cardiograph, etc.) the guiding-line, and, consequently, the required ordi-

nate, is the arc of a circle whose radius is equal to the length of the lever. Figs. 3143 to 3148 are examples of such measurements. If the rate of movement of the travelling surface is known, the distance in time between two points in the curve can be measured by the distance in space between the points at which the respective ordinates cut the abscissa. In Fig. 3143 the time of distention of the artery, *a b*, is measured by the distance *a* B on the abscissa; the time between the apex, *b*, and the summit of the dicrotic wave, *f*, is measured by B F, etc. The relative height of the events on the curve above the base-line can similarly be measured on the guiding-line G *a* as an abscissa, by ordinates drawn upon it from the respective points parallel to the base-line.

Very accurate measurements are obtained by causing the lever of the sphygmograph to write on a surface fixed upon a vibrating tuning-fork. Landois also measured his curves under the microscope by means of an ocular micrometer. The writer has obtained good results by magnifying the curves registered on transparent slides by means of the magic-lantern.

It is not always easy to determine the exact location in the curve of the points to be measured. The readiest method to determine *d* and *f*, the summits of the predicrotic and dicrotic waves, is to draw parallel with a line connecting *c* and *e* (for *d*) or *e* and *á* (for *f*) a tangent to the elevation; the point of contact must be the highest point in the elevation (because the wave is superimposed upon the line of descent, which, but for this wave, would have been straight, or nearly so); but it is not always the point most distant from the base-line.

The period of ascent—indicating the duration of influx of blood into the artery—occupies only a portion of the ventricular systole. It is preceded by a period of less than one-tenth second from the beginning of the ventricular contraction to the opening of the aortic valves; and it is followed by a period of about .069 second from the time when the influx ceases until the closing of the aortic valves. Hence, the systolic portion of the curve (corresponding to the period between the first and second sound of the heart = about one-third second) begins before the up-stroke and terminates at some point in the down-stroke. This point, in successful tracings of the carotid pulse is found in the notch preceding the first secondary elevation, caused by the closing of the aortic valves. In the radial curve this wave is commonly absent; in the majority of cases (if not always—see foot-note on p. 86) it coincides nearly with the beginning (or the summit, Keyt) of the predicrotic wave; it is this point, not the so-called "aortic" or diastolic notch, that may serve to mark approximately the end of the cardiac systole.

The period from the beginning of the ventricular contraction to the opening of the aortic valves, the interval between the ascent of the cardiogram and the ascent of the pulse-curve—the *presphygmic interval* of Keyt[1] (*syspasis*, Garrod)—is said to have a mean duration of .087 second by Czermak; .10 to .11 second by Mosso; .073 by Rive; (only .02 to .03 by D'Espine?); .085 by Landois; about .08 sec. (with a pulse-rate of 75 per minute) by Keyt. The latter author made it the subject of extended investigation and demonstrated the importance of a knowledge of it in both physiological and pathological conditions. It is subject to considerable variation, and "varies inversely with the pulse-rate," "being shorter with frequent and longer with rare pulsations." Pathologically, the interval is lengthened, especially by slow ventricular contraction, by high arterial pressure, and by mitral insufficiency; shortened by quick contraction of the heart, by low arterial pressure, and by aortic insufficiency. In fever, with a fairly strong heart, the interval is short.

The duration of the ascent differs somewhat in individual curves, not only of pulses of different frequency and character but also of the same tracing. In typical radial curves measured by Landois its mean duration was .097 second; in a number of radial curves written with my Marey's instrument, the period of ascent *a* B = .0903 second; in some curves by Pond's sphygmograph the average *a* B = 0.12 second. The variations in the duration of the ascent are not as great as of the descent, nor proportioned to them. A frequent pulse (of short duration) does not necessarily have a short period of dilatation—in other words it may be *tardus* as well as *celer*.—

It is evident that the form of the pulse-curve permits us to draw conclusions as to the conditions which contribute to determine it; these are, chiefly, the degree of tension of the arterial wall, the volume of blood added by each systole, and the force with which it is injected. Increased *tension* alters the form of the curve in the direction of the *p. tardus et durus* and diminishes its height; diminished tension produces a *p. celer et mollis* and increases the height of the curve, the area in each case remaining the same. Greater *volume* of blood likewise produces the form of the high-tension pulse, increasing at the same time the height and the area of the curve; lessened volume diminishes the area and makes the pulse quicker and lower. Increased *force* of systole (as in simple hypertrophy) causes a larger and quicker pulse; with simultaneous increase of volume of blood propelled the curve is still higher, or at least as high, but perhaps more tardy, and the area of the curve is greater. Diminished force alone makes the curve tardier and smaller; combined with diminished volume the curve becomes quicker and smaller, or at least not higher, and the area of the curve less. ——

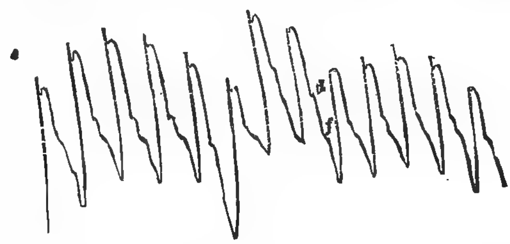

FIG. 3149.—Tracing of an Abdominal Pulsation. 116. (Marey's.)*

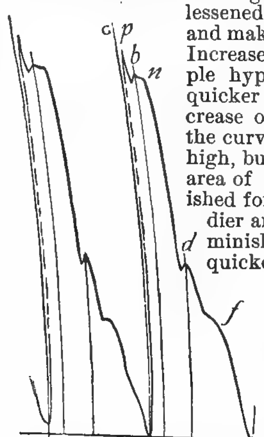

FIG. 3150.—Two Curves of Fig. 3149 Enlarged × 2 by Aid of Magic-lantern.

In Different Arteries the pulse registers different forms of curve. The tracings secured by Penzoldt[18] in a case of fissure of the sternum from the *ascending aorta*, revealed an anacrotic elevation—probably due to the movement of the auricles being communicated to the lever of the instrument—and near the apex an elevation evidently corresponding to the closing of the semilunar valves, but no other elevations in the down-stroke. I have lately obtained tracings from an abdominal pulsation, so well defined that they can fairly be taken as reproducing the pulse movements of the *abdominal aorta.**

The curve of the *carotid* pulse is characterized by considerable height, a steep up-stroke, an acute apex; on the down-stroke, close below the apex, is found the elevation attributed to the sudden closing of the aortic valves, commonly coinciding with the first elastic oscillation, and

* Mrs. M., fifty-seven years of age, washerwoman; greatly emaciated and worn by hard toil; irritable heart; pulse-rate, 116; pulsation above umbilicus so forcible and so distinct to inspection and palpation as to have suggested aneurism. It was equally accessible to the sphygmograph, as the figures show. They reveal a forcible percussion-stroke, *p* (see footnote on page 86); the true apex, *b*, is soon followed by the wave of the aortic valves, *n*, at almost the level of the apex, and the down-stroke is marked by both predicrotic, *d*, and dicrotic wave, *f*. The measurements agree very well with this interpretation. I have not met in literature with any other curves of the abdominal aorta. The tracing given by Ozanam (La Circulation et le Pouls, Paris, 1886) on page 694 is, of course, ludicrously inexpressive, as are, indeed, all the curves in that fearful and wonderful book.

constituting the predicrotic wave; the dicrotic wave is small, owing to the high tension in the carotid, and oc-

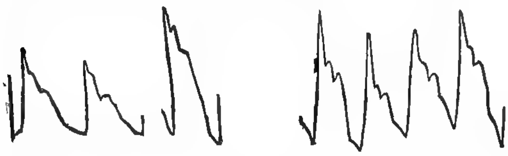

FIG. 3151.—Normal Carotid Curves; the first three after Eulenburg, the last four after Landois. (Marey's.)

curs early in the descent, owing to the nearness of the artery to the heart. The *subclavian*, and the more accessible *axillary*, arteries yield a similar tracing with a larger dicrotic wave. The pulse of the *brachial* artery in

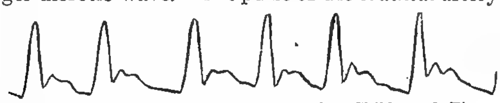

FIG. 3152.—From Right Brachial Artery of a Child aged Five. 90. (Pond's.)

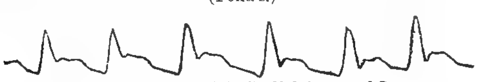

FIG. 3153.—From Right Radial Artery of Same.

the bend of the elbow differs from the radial pulse chiefly by its greater amplitude. In the curve taken from the *femoral* artery, the predicrotic wave is large and so high up as to delay the descent and blunt the apex, so that the curve looks much like a radial curve of high tension; but the dicrotic elevation is low down in the curve.

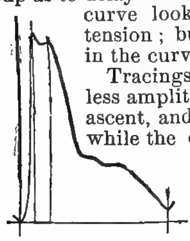

FIG. 3154.—From the Femoral Artery. (Marey's.) × 2.

Tracings from the *dorsalis pedis* artery have less amplitude than the radial, a more slanting ascent, and a distinct but late dicrotic wave, while the elastic oscillations are, as a rule, imperfect and weak; the pressure of the instrument easily prevents their expression in the trace, and we find the predicrotic wave only in very delicately written curves. Tracings can be taken from other accessible arteries, as posterior tibial, temporal, etc.; in a case of overactive heart, I have obtained one from the digital artery of the middle-finger.

In Different Individuals, the normal pulse differs widely in frequency, celerity, magnitude, and degree of tension. These personal variations are, however, remarkably persistent, so much so that the same person, under ordinary circumstances, always yields the same form of pulse-curve. Even when disease, as an acute fever, has altered the aspect of the tracing in all essentials, the curve after convalescence assumes again the qualities characteristic of the individual's pulse previous to the illness. Various physiological states modify the curve for the time being, in accordance with their well-known influence on the circulation. Thus, muscular labor, digestion, elevation of temperature make the pulse larger, softer, and more frequent. Cold, whether applied to the entire body or only to the part the artery of which is under examination, causes a smaller and harder pulse by vaso-constriction and rise of tension. Sex has no influence on the form of the pulse-tracing. Age, on the contrary, affects it in a conspicuous manner. *In the child*, the pulse-curve is marked only by distinctness of the elastic elevations, especially a well-developed and often high-placed predicrotic wave, while the dicrotic wave is but little prominent. The regularity of rhythm is more easily disturbed in the child than in the adult.

The *Pulse of the Aged* is very characteristic. The vascular changes of senile life do not set in at the same age in all persons, but sooner or later, almost certainly after the sixtieth year, they find expression in the pulse-curve. They consist essentially in a loss of elasticity of the arterial wall by gradual atheromatous changes. The rising blood-wave dilates the arterial tube but slowly, at least in the higher degrees of atheroma; once distended, the less elastic artery does not contract with the promptness required for the normal celerity of the pulse, but remains distended for a while; hence the apex is no longer sharp, but rounded or even flattened, all the more so because the predicrotic wave is large and near, or on a level with, the apex, owing to the high blood-pressure developed by the systolic filling of the rather unyielding vessel. Subsequent elastic elevations are absent. The dicrotic wave is present in moderate degrees of atheroma, but in most cases it is small, and in some almost obliterated. The pulse is eminently *tardus*. The pulse of the

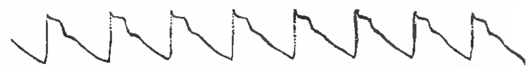

FIG. 3155.—Male, Seventy-nine Years of Age. 80. (Marey's.)

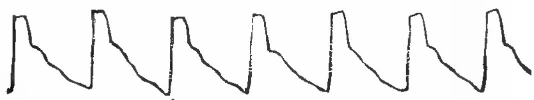

FIG. 3156.—Male, Sixty-two Years of Age. 66. (Marey's.)

FIG. 3157.—Male, Ninety-two Years of Age. 70. (Marey's.)

aged must not be confounded with a simply hard pulse; it retains its character of tardity—the labored ascent and rounded apex—even when the blood-pressure is diminished and the dicrotic elevation reappears with distinctness, as in fever. But when the heart is hypertrophied, the pulse of the rigid artery may have a steep ascent and an acute apex, while the down-stroke retains the characters described.

A sphygmographic tracing—sphygmogram—consists of a series of pulse-curves, which enable one to observe the rate of the pulse, its rhythm, and rapid fluctuations in the mean blood-pressure. The average pulse-rate is more readily, and quite as accurately, counted by the watch; slight variations in it are, however, best measured in the tracing. Rhythmical fluctuations of the blood-pressure and of the pulse-rate are caused in the normal tracing by the respiratory movements. All other changes in rhythm are pathological.

The Influence of the Respiration on the pulse is barely perceptible in a tracing taken during quiet, superficial breathing. As a rule, the basal points of all the curves of such a tracing are in a straight line parallel to the base line; but when the respiration is deep and slow,

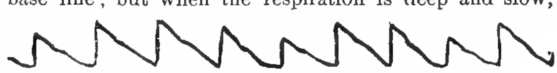

FIG. 3158.—Male, aged Thirty-two. 71. (Marey's.)

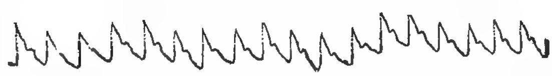

FIG. 3159.—Male, aged Thirty-eight. Chronic Parenchymatous Nephritis. Dyspnœa at the time. 116. (Marey's.)

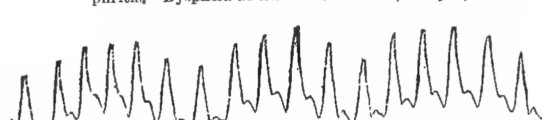

FIG. 3160.—Female, aged Thirty-two. Tachycardia. Subclavian artery. 140. (Pond's.)

the line connecting the basal points—the "respiratory line"—is often not straight, but undulating in unison with the respiratory movements. In such case, a line connecting the apices of the curves is still more undulating, because the pulses are largest on the summits

of the respiratory curves (as in Fig. 3160)—*i.e.*, the pulses coinciding with expiration are the largest; they also have a smaller and higher-placed dicrotic elevation; whereas those which coincide with inspiration are smaller, have a larger and lower-placed dicrotic wave, and a smaller predicrotic wave; they "begin to be dicrotic." Thus is expressed in the pulse-tracing the fact that the arterial blood-pressure rises during expiration and falls during inspiration. The inspiratory pulses are also somewhat more frequent then the expiratory pulses, the slowing beginning a little before the expiration and lasting a little beyond it (Penzoldt). This is particularly evident during voluntary slowing of the respiration. When, however, the breath is held in deep inspiration, the pulse-curve gradually increases in length (becomes less frequent), in height, and in area, and assumes the form of high tension.

The respiratory influence on the curves is plainly seen, as a rule, in the pulse of children, and is exaggerated during sleep—so much so that in many healthy children it is perceptible to palpation, and the pulse seems irregular, approaching in character the (pathological) *pulsus paradoxus* (see below). It is a clinical fact of some importance that this irregular pulse in a sleeping child is not a sign of disease.

The Pulse in Disease.—The more prominent alterations which the pulse suffers under morbid conditions may be classified as, (1) changes in tension, (2) changes peculiar to certain diseases of the heart and great vessels, (3) local changes in individual arteries or vascular territories, (4) changes of rhythm, and (5) changes of frequency.

1. In health, the average arterial tension differs widely in different individuals, and considerable differences in this respect are compatible not only with health, but with bodily vigor. But it will be noted that in case of either extreme the pulse is rather large; a small and soft pulse is frequently associated with low energy, a small and hard pulse is more often observed in persons of irritable habit and neurotic tendencies. Still, the individual variations are so large that in the absence of other signs they are of small prognostic value.

Moreover, in healthy persons, during rest and under seemingly unvarying conditions, the tension of the arteries is subject to frequent changes in degree, so that successive series of curves, taken with an instrument that remains in position for some time, show differences of form which must be ascribed to alterations of "tone" by vaso-motor influences, to which the play of mental activity and of emotions greatly contributes.[19] This mobility of the state of muscular contraction of the arteries is so constant in persons of vigorous health, that G. v. Liebig [20] considers its absence a sign of diagnostic value.

Among the influences which alter the tension more decidedly are cold and heat. A cold bath, a chilly room furnish opportunities for observing the increase in tension; a warm atmosphere, the elevation of temperature after a full meal or after vigorous exercise, at once alter the pulse-form in the opposite direction, even to dicrotism.

The alterations in the direction of lowered tension are seen in their higher degrees in

Dicrotism.—The dicrotic form of pulse results whenever the predicrotic elevation disappears, and the dicrotic wave is enlarged. Both changes occur when the blood-pressure falls sufficiently low, provided the elasticity of the arterial walls is intact. A dicrotic pulse is a pulse of low tension. Rigidity of the artery, as in atheroma, tends to prevent dicrotism. Sudden influx of blood, due to a short and energetic systole, assists in the development of the dicrotic curve, but is never alone competent to cause dicrotism, whose *conditio sine qua non* is lowered blood-pressure, especially when caused by relaxation of the vascular wall.* The conversion of a curve of fair tension into a dicrotic curve can often be seen in arhythmical tracings, as in Fig. 3194 (magnified in Fig. 3145).

The most conspicuous and best known example of the dicrotic pulse occurs in fever. Under the influence of greatly elevated temperature, the peripheric arteries relax, the arterial blood-pressure falls, and the pulse becomes exquisitely dicrotic, as has long been known in the case of typhoid fever, but is true of all febrile diseases. During the initial chill of an acute paroxysm, the pulse is small and hard; as the chill passes off it becomes large, full, and bounding (*magnus, plenus, celer*), even hard in the beginning of inflammatory fevers; but soon it becomes soft, easily compressed, and with increasing relaxation of the smaller arteries the radial pulse shows a dicrotism distinct enough to be appreciated by the finger. The influence of lessened tension in causing di-

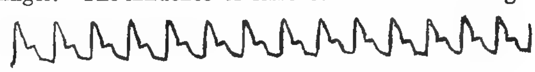

Fig. 3161.—Incipient Phthisis. Temperature, 99.4°; pulse, 114. (Marey's.)

Fig. 3162.—Catarrhal Fever. Temperature, 100.2°; pulse, 94. (Marey's.)

Fig. 3163.—Renal Dropsy; Low Tension. Temperature normal; pulse, 84. (Pond's.)

crotism is enhanced by a short and quick systole, and by the greater frequency of the pulse. A high pulse-rate, as such, does not cause dicrotism, but it assists in bringing about modifications in the curve that are characteristic of the degrees of dicrotism. When the normal curve passes into the dicrotic, the predicrotic wave disappears, the first part of the down-stroke is steep and long; the dicrotic wave, while it grows in height, is delayed; the diastolic notch approaches the base line, as in Figs. 3161 to 3163; the pulse is *sub-dicrotic*. With still lessening tension, the great notch reaches the base line, as in Figs.

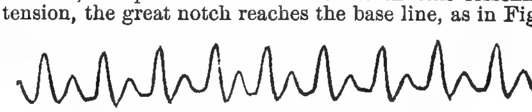

Fig. 3164.—Typhoid Fever, Third Week. (Pond's.)

Fig. 3165.—Phthisis Pulmonalis. Temperature, 102.3°; pulse, 114. (Pond's.)

3164, 3165, which exhibit *full dicrotism*, or even falls below the base line, as in Figs. 3166, 3167, the *hyperdicrotic* pulse. In the first instance, the lever in the second por-

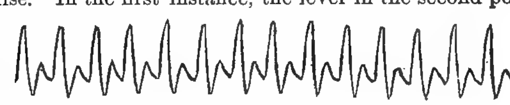

Fig. 3166.—Continued Fever. Temperature, 103.2°; pulse, 124. (Pond's.)

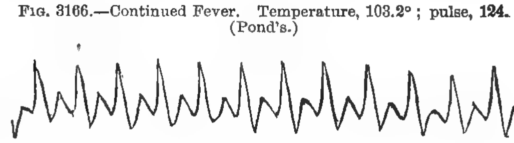

Fig. 3167.—Typhoid Fever. Temperature, 103.4°: pulse, 124. (Pond's.)

tion of the descent falls lower than in the first portion; in the fully dicrotic pulse, partly owing to greater fre-

* For it is by no means certain that the ready and invariable conversion of a normal pulse into the dicrotic form in fever is due solely to diminished blood-pressure; the altered innervation, or a direct influence of the febrile temperature upon the muscular coat, is probably a positive factor in this process, as well as an (indirect) means of reducing the blood-pressure. Changes in the degree of dicrotism do not always run parallel with changes in blood-pressure; dicrotism sometimes disappears without a corresponding rise of pressure.

quency of the heart's action, the following systole raises the lever when it has reached a point as low as the diastolic notch; in the hyperdicrotic pulse, the lever is raised by a still earlier systole before it has reached that point; the great notch lies below the line connecting the basal points. If the frequency of the pulse becomes still greater, the succeeding systole lifts the lever when it has reached the summit of the dicrotic wave; the lever has not time to make a second descent, and the pulse has made only one elevation, one beat—is *monocrotic*, as in Fig. 3168. Thus the degree of dicrotism depends partly

FIG. 3168.—Typhoid Fever. Temperature, 104.8°; pulse, 160. (Marey's.)

on the delay of the enlarged dicrotic wave and the deepening of the great notch, and partly on the frequency of the pulse. When, however, the usual parallelism between the temperature, the relaxation of the peripheric vessels, and the beat of the heart is disturbed (as by medication), it may happen that even very great frequency

FIG. 3169.—Typhoid Fever. Under Antipyrin. Temperature, 100.8°; pulse, 140. (Pond's.)

does not produce a monocrotic pulse (see Fig. 3169). On the other hand, monocrotism can occur only in a very frequent pulse.

The degree of dicrotism corresponds in a measure to the degree of fever; the higher the temperature, the lower the tension; as the fever rises, the pulse-curve gradually passes through the successive changes of form described. With a temperature of 39° to 40° C. (102° to 104° F.), we may confidently expect, in acute fevers of previously healthy adults, a fully dicrotic pulse; beyond it the curve becomes hyperdicrotic or even monocrotic. This parallelism is, however, not at all constant, but subject to many influences, one of which is the frequency of the pulse, another the strength of the patient. In feeble persons, in chronic febrile diseases, in the later stages of acute fevers, even, the various phases of dicrotism are reached with lower temperatures; thus, at 39° C. (102° F.), a phthisical patient may yield a hyperdicrotic curve, while a pneumonic or typhoid patient may, at the same temperature, have a sub-dicrotic pulse. In individuals who previously had a high-tension pulse, *i.e.*, whose usual pulse-curve was farther removed from the dicrotic pulse than is the normal, fever develops the phases of the dicrotic pulse only with higher temperatures.

As the fever abates, the pulse-form gradually returns to the normal, but not quite as rapidly as the temperature sinks; and sometimes the pulse remains subdicrotic during convalescence, or shows the form of normal tension only with subnormal temperatures.

By the finger, dicrotism is recognized most easily when the difference in height between the two waves is least, and the pulse is neither very frequent nor very small—in the fully dicrotic pulse of undulating character. The dicrotic beat is also perceived with distinctness in a subdicrotic pulse of moderate frequency. In the hyper-

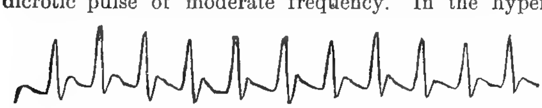

FIG. 3170.—Pulmonary Hæmorrhage. Temperature normal; pulse, 100. (Pond's.)

dicrotic pulse the second beat is felt as a grace-note to the succeeding primary beat, *p. caprizans*.

While fever furnishes the most pregnant examples of low tension pulse, all other causes of low blood-pressure have more or less dicrotic forms of pulse. High degrees of anæmia, collapse, sudden losses of blood, fatty heart, and other conditions of cardiac debility, alter the curve in the same direction. Drugs which reduce the blood-pressure rapidly are capable of causing dicrotism, notably amyl-nitrite.

The Pulse of High Tension is caused mainly by obstructed outflow toward or through the capillaries, as by contraction of the arterioles. It is marked by high position and large size of the predicrotic wave, and by small size of the dicrotic wave. It can be produced

FIG. 3171. Digitalis. 52. (Marey's.)

artificially by drugs which raise the blood-pressure, by none more readily than digitalis (Fig. 3171).

Among diseases, lead-poisoning, gout, and Bright's disease, especially the first stage of acute nephritis and contracted kidney, furnish the most common examples of high-tension pulse. In acute nephritis, the pulse is often hard from the beginning and before hypertrophy of the heart has been developed, and retains this character for some time. In chronic parenchymatous nephritis we commonly miss this symptom (compare Fig. 3159). But in contracted kidney, especially the genuine arterio-sclerotic form, the high-tension pulse (*durus*, *tardus*, and often *magnus*) is an early, sometimes the earliest, sign, and apt to persist until near the fatal end,

FIG. 3172.—Female, aged Twenty-two. **Contracted Kidney; Retinitis.** 74. (Pond's.)

FIG. 3173.—Male, aged Sixty. Contracted Kidney. 56. (Marey's.)

enhanced or modified by hypertrophy of the left ventricle (Figs. 3172 and 3173).

Hypertrophy of the heart, alone, does not produce the high-tension pulse; *i.e.*, the blood-pressure is not necessarily high between the beats. The energetic contraction of a large ventricle, especially when the pulse is not frequent, causes a large pulse; but if other causes of high tension are absent, if the outflow through the capillaries is free, the pulse does not show the tardity of the common *p. durus et tardus;* the up-stroke is very steep,

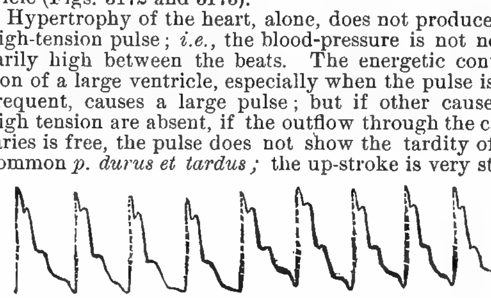

FIG. 3174.—Male, aged Forty-eight. Hypertrophy of Heart. 62. (Marey's.)

and although the predicrotic wave may be large and near the apex, the fall of the lever immediately afterward is sudden, the dicrotic wave apt to be low down and fairly developed. Thus the pulse of hypertrophy can usually be distinguished from the *p. tardus* of Bright's disease and of atheroma.

Pregnancy has been found to induce a high-tension pulse; and in some anæmic patients, the arterial tension is unexpectedly high. A certain class, too, of nervous women of spare habit, suffering from paroxysmal painful affections, vague and shifting neuralgic pains or more pronounced neuralgias, megrim and other headaches, present a uniformly tense but small pulse. This is certainly not the pulse of high tension which precedes arterio-sclerotic kidney disease, but is owing to irritation or abnormal irritability of the vaso-constrictor nerves. It has proved valuable to me in arriving at indications for treatment.

2. *Valvular Disease of the Heart*, modifying the pulse-

movement at its source, impresses its characters on the curve, though not so specifically as to enable one to diagnosticate valvular lesions from the pulse-curves, even with the aid of cardiograms; the sphygmograph only furnishes evidence of the same kind, and of the same value, as that which is obtained by auscultation and percussion of the heart. *Mitral regurgitation*, so long as it is perfectly compensated by the strength of the heart, simply lowers the blood-pressure (the ventricle not discharging all it contains into the aorta), and yet frequently

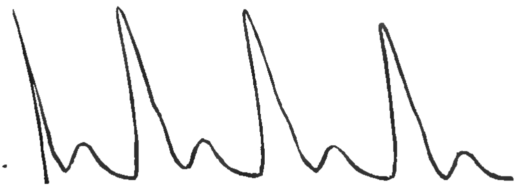

FIG. 3175.—Mitral Insufficiency, Compensated. 90 to 100. (Burdon-Sanderson's.)

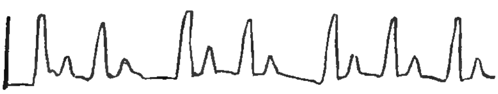

FIG. 3176.—Mitral Insufficiency, not Compensated. 75. (Pond's.)

increases the height of the curve (by an energetic systole); hence makes a soft and often large pulse. When compensation is (temporarily or permanently) disturbed, the pulse becomes frequent and irregular in rhythm, as will be described below. In *mitral stenosis* the pulse is small, soft, and sometimes frequent; when the heart's muscular power becomes impaired, it grows more or

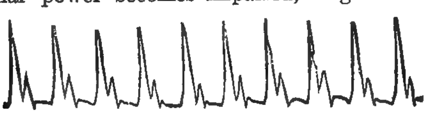

FIG. 3177.—Aortic Regurgitation. 98. (Pond's.)

less irregular. Irregularity of pulse is a mark of mitral affections, rather than of aortic lesions. *Aortic regurgitation* gives, of all valvular defects, the most characteristic curve. If perfectly compensated, it can be so only by hypertrophy of the ventricle, and this tells its tale in the curve; but if the incompetency of the valves is considerable and compensation incomplete, signs of the regurgitation are visible in the sphygmogram. The hy-

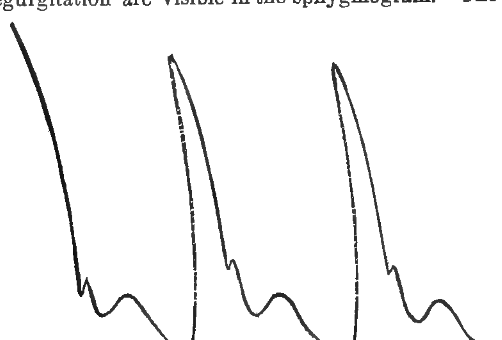

FIG. 3178.—Aortic Regurgitation with Mitral Insufficiency, the Former Predominating. 80. (Burdon-Sanderson's.)

pertrophy causes a high and very steep up-stroke; the curve is always large and the descent is rapid at first, because during the diastole blood flows back into the ventricle as well as onward to the capillaries; the predicrotic wave is usually low down and of varying size, often small; the dicrotic wave is small and well down toward the base line. The artery, then, is quickly and forcibly distended, and as quickly contracts again. A pulse of this character is easily recognized by palpation; it is eminently *celer*, quick to come and go, and yet large and strong, giving the impression of the rebound of a

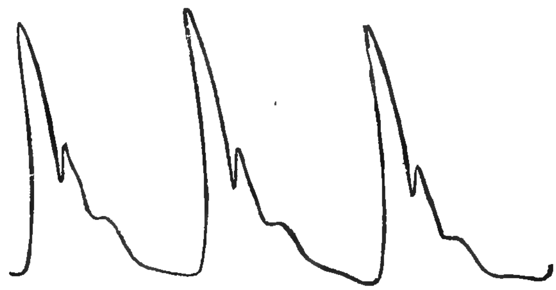

FIG. 3179.—Aortic Regurgitation. 76. (Burdon-Sanderson's.)

hammer, or of a bullet passing under the finger; the "shotty" or "bullet" pulse. It is usually quite regular. The normal delay of the pulse as compared with the heart's impulse is abnormally shortened; Keyt[21] deems this symptom so characteristic, that in the absence of fever it is pathognomonic of aortic insufficiency of high

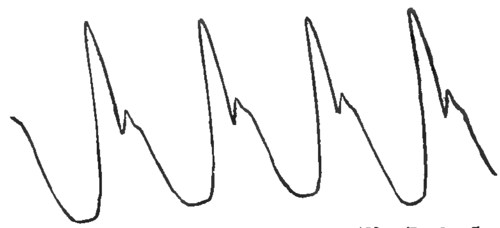

FIG. 3180.—Aortic Regurgitation, Traumatic. 120. (Burdon-Sanderson's.)

degree. Sometimes the up-stroke is interrupted by an elevation, which Landois interprets as an expression of the auricular systole that makes itself felt through the partially open aortic orifice.

The pulse of *aortic stenosis* is commonly regular, often small, and always very tardy, as its mode of formation

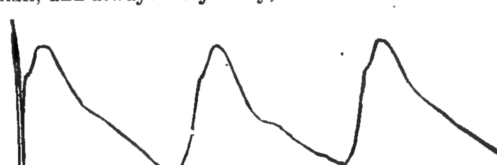

FIG. 3181.

FIG. 3182.

FIGS. 3181 AND 3182.—Aortic Stenosis. 80. (Burdon-Sanderson's.)

FIG. 3183.—Aortic Stenosis. 78. (Pond's.)

explains; the probably hypertrophied ventricle presses a limited volume of blood into the artery with difficulty, hence slowly; therefore the up-stroke is slanting, and the entire systolic portion of the tracing is prolonged; the "apex" is lower than the summit of the curve, and constitutes an ("anacrotic") elevation in the ascent. The smallness of the pulse often contrasts strongly with a forcible impulse of the heart.

Valvular defects of the right heart can have only an indirect effect on the arterial pulse-curve. Combinations of two or more valvular lesions do not yield curves as transparent in their meaning as those of pure cases; yet

even here, comparison of the pulse records with the cardiograms and the results of physical exploration is a material help in diagnosis.

Disease of the Arteries manifests itself chiefly in the hard pulse of arterio-sclerosis (as in chronic Bright's disease), and in the tardy pulse of atheroma. The influence on the pulse of atheromatous disease has been noticed in describing the pulse of the aged, the chief characteristic of which is its tardity. In high degrees

FIG. 3184.—Atheroma. 45. (Burdon-Sanderson's.)

of atheroma we witness the appearance of an anacrotic elevation (Fig. 3184).

Anacrotic Elevations—secondary waves in the line of ascent (Figs. 3181 to 3184)—are found only in disease; they require for their formation a lengthened and labored influx of blood, either by reason of great volume of blood pressed in, as in dilatation of the left ventricle, or because of an unyielding artery, as in Bright's disease, in atheroma, etc. Often both conditions concur. The anacrotic pulse is always a *p. tardus*. The occasional appearance of anacrotism in the pulse of paralyzed parts (when the vaso-motor nerves are included in the paralysis), Landois explains by the loss of active contractile power ("tone"), slowing of the circulation, venous and capillary stasis, and hence increased impediments to the influx of blood into the arteries. The anacrotic wave which sometimes (rarely) arises in the pulse of aortic regurgitation has an entirely different origin in the transmission of the wave of the auricular systole through the open aortic orifice.

3. *Local Differences in the Pulse.*—At times the pulse of one artery is found to differ from that of the corresponding vessel of the other side—*p. differens*. Apart from anatomical anomalies, the differing pulse is caused either by (more or less local) changes in innervation or by mechanical means. Among the former class of causes—which are very numerous—is cold applied to the part; an arm exposed to cold yields a radial pulse of higher tension and less height than its warm fellow. A dicrotic pulse confined to one artery or limb indicates paralysis of its vaso-motor nerves. In hemiplegia the paralyzed side commonly gives a softer pulse, with a more rounded apex,

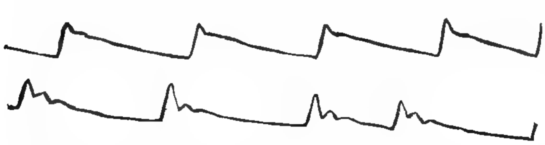

FIG. 3185.—Hemiplegia (cerebral), Recent. Upper trace from left radial, normal; lower trace from right radial, paralyzed. 54. (Pond's.)

a high predicrotic and a feeble dicrotic wave; sometimes, indeed, the otherwise rare combination of *p. mollis et tardus*. Sometimes the tardity is more pronounced, even to anacrotism; the primary wave does not reach high enough to form the apex.

Among the mechanical causes of the differing pulse are compression of the artery, as by tumors, cicatrices, adhesions, etc.; obstruction of the venous current by similar means; and aneurisms situated between the heart and the vessel examined, which do not interfere with the circulation of the other side.

Smallness of the left radial pulse, as compared with the right, has been observed by Traube[22] in cases of pericardial exudation. The phenomenon is explained by pressure of the enlarged pericardial sac on the arch of the aorta. A greatly dilated heart has been found to produce the same effect, probably in the same manner.[23]

4. *Altered Rhythm; Allorhythmia cordis; Arhythmia cordis; Intermittent Pulse.*—While the normal tracing, aside from the slight modifications of rhythm produced by normal breathing, shows pulses of almost equal duration and magnitude, many deviations are met with in disease. A frequent occurrence is the feebleness or entire suspension of a ventricular contraction, resulting in the dropping of one beat of the pulse, now and again, sometimes at regular intervals, sometimes irregularly—

FIG. 3186.—Intermittent Pulse. 84. (Pond's.)

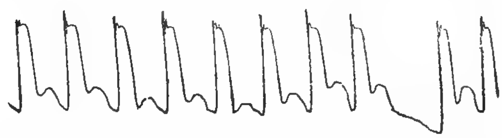

FIG. 3187.—Intermittent Pulse. Kidney disease consequent upon enlargement of the prostate and cystitis, in a patient aged eighty-three; fever. Temperature, 101.6°; pulse, 92. (Marey's.)

the *intermittent pulse*. True intermittence, due to actual absence of systole—*p. deficiens*—can be recognized by absence of cardiac impulse and of both sounds. The systole may take place, however, yet not be strong enough to open the aortic valves against the blood-pressure in the aorta, and hence cause no wave in the arterial system—*p. intermittens*; or it may have force to cause a small wave, registered by the sphygmograph, but not percepti-

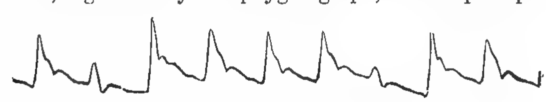

FIG. 3188.—Pulsus intercurrens. 77. (Pond's.)

ble to the finger, or only felt as a very feeble beat—*p. intercurrens* or *intercidens*.

In some cases feeble systoles occur with great regularity; *e.g.*, they alternate with strong contractions, causing an alternation of strong and feeble pulses—*p. alter-*

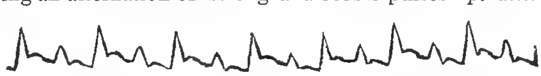

FIG. 3189.—Pulsus alternans. Apoplexy. 110. (Pond's.)

FIG. 3190.—Pulsus alternans. Chronic Nephritis. 140. (B. Sanderson's.)

nans. The feeble pulses may be so small as not to be easily perceived by the finger, so that a pulse-rate of 80 is counted as 40. Or the feeble systole may take place soon after a cardiac contraction of ordinary force; the result is that the pulses appear in pairs, in which the first has a high ascent and a short descent, the second a short ascent and a long down-stroke—*p. bigeminus*. Sim-

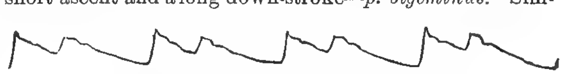

FIG. 3191.—Pulsus Bigeminus. (Pond's.)

ilarly, one strong systole may be followed by two feeble ones in quick succession, making a *p. trigeminus*, etc. In certain cases the second contraction, which cuts into the diastole of the first, working with an almost empty ventricle, has not strength to open the aortic valves, and therefore fails to cause a pulse—an alternately intermittent pulse, as it were; one pulse to two systoles, or, rather, a bigeminous action of the heart in which the futile second twin contraction makes no pulse.

In the case from which Figs. 3192 and 3193 were taken, three sounds of the heart were heard to each pulse at the wrist, the third sound being the systolic sound of the fu-

tile systole, which was not followed by a diastolic sound. This condition has been described and much discussed[24]

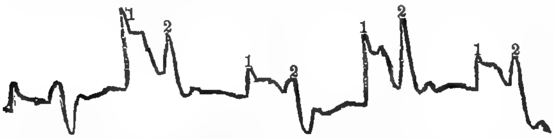

Fig. 3192.—Cardiogram of Bigeminous Action of Heart. 1, 2, Indicate the first and second systole of each twin pair; the lower phases correspond to inspiration, the higher to expiration. Contractions of heart, 80. (Marey's sphygmograph.)

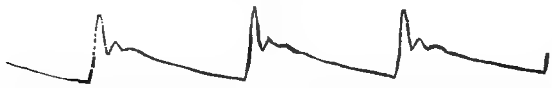

Fig. 3193.—Sphygmogram of Radial Pulse of Same Individual. Pulse-rate, 40. (Pond's.)

under the name of intermittent hemisystoly of the heart,* and of *Herzbigeminie.*

In some cases the pulses vary in regularly graded groups, as in Fig. 3194, where an ordinary pulse of fair

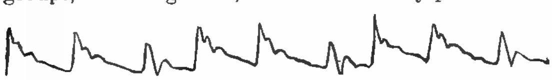

Fig. 3194.—Male, aged Twenty-eight. Abuse of Tobacco. 77. (Pond's.)

tension is followed by a smaller and softer one, and that again by a still smaller, still softer, dicrotic pulse—such groups of three recurring again and again.

All the foregoing varieties of rhythm have been spoken of as *allorhythmia cordis*—altered rhythm, in which the inequalities of size as well as of sequence follow certain rules or types—in distinction to the quite irregular action of the heart that wipes out all rule and rhythm—*arhythmia*, *ataxia*, or *delirium cordis*, of which Figs. 3195 to 3198 furnish examples. In Fig. 3198, from a

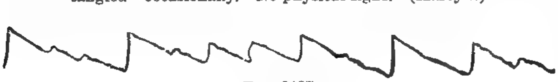

Fig. 3197.

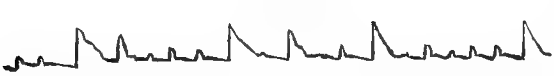

Fig. 3198.

Figs. 3197 and 3198.—Male, aged Sixty-five. Atheroma; Disease of Coronary Arteries; Angina Pectoris. (Marey's.)

patient with atheroma, including the coronary arteries, with myocardial changes, who suffered most violent attacks of stenocardia, one full beat is succeeded by a variable number of feeble ones, and the very frequent pulse is at times utterly irregular.

All these phenomena of arhythmia and allorhythmia are of similar origin; their fundamental cause is disturbed innervation, arising either within the heart (from lesions of structure or of circulation in the heart's muscle) or in the vagus or sympathetic, or coming through these nerves from the cerebral centres—either directly, as in cerebral disease, disease of the pneumogastric nerve (compression by tumors, scrofulous glands, etc.), and in psychical disturbances; or reflexly (as in lesions of digestion, disease of the liver); or as a result of intoxication (by tobacco, tea, or coffee). These causes operate more readily upon the already enfeebled or overtaxed heart; hence we meet with them in anæmic persons, in convalescents from acute diseases, in valvular lesions which have passed the stage of compensation. Complete arhythmia is seen most frequently in chronic diffuse myocarditis,[25] of which it is almost characteristic when persistent and not merely paroxysmal. In uncomplicated disease of the mitral orifice it occurs more frequently in paroxysms and varies much in degree; digitalis tends to diminish the irregularity, while in chronic myocarditis the same remedy has no influence over it.

A disturbed rhythm of an altogether different kind is the *pulsus paradoxus* of Kussmaul.[26] It consists in a diminution or total suppression of the pulses which coincide with inspiration. Two distinct groups of cases, of entirely different origin, show this phenomenon. One group is owing to obstruction to the free ingress of air into the lungs, augmenting the inspiratory effort and thus intensifying the inspiratory lowering of pressure within the thorax—to such an extent that the proper filling of the left ventricle is prevented, and the latter, during inspiration, throws into the aorta an amount of blood too small to cause a pulse-wave in the radial artery. This symptom has been observed in stenosis of the air-passages (croup, paralysis of the crico-arytenoid muscles, compression of the trachea by tumors), as well as in a case of capillary bronchitis (Bäumler[27]). In this group the phenomenon is simply an exaggeration of the (normal) influence of the respiratory movements.

In the second group of cases, the paradoxical pulse results from mechanical compression of the aorta by means which are brought into action only during inspiration. This was first observed (by Kussmaul) in cases of mediastinal adhesions of the pericardium, the fibrous bands being put upon the stretch whenever the sternum makes its forward movement in inspiration, and, by constricting the aorta, obstructing the flow of blood through it. In such case the same compression is exerted upon the venæ cavæ, and manifests itself in a swelling of the jugular veins with each inspiration. The combination of the latter symptom with the *p. paradoxus* is pathognomonic of fibrous mediastino-pericarditis. The paradoxical pulse alone is not so characteristic, for it has been found (Bäumler, Hindenlang[28]) in cases of hydropericardium without fibrous adhesions; here, however, the veins of the neck were permanently distended, not more during inspiration than during expiration.

5. *Morbid Changes in the Pulse-rate.*—The physiological conditions which modify the frequency of the pulse, when exaggerated in disease, will naturally change the rate in the same direction. Increased muscular activity, as in tetanus, increased chemical change in muscle or in the tissues generally, as in fever (elevation of temperature, etc.), raise the pulse-rate; *vice versa*, lessened muscular activity and the lessened production of heat in convalescents from acute diseases lower the pulse-rate. An apparent exception is observed in convalescence from typhoid fever, when the frequency of pulse remains high even in the absence of all morbid symptoms (Traube). In general, it may be borne in mind that in disease, as in health, low blood-pressure commonly goes with frequent pulse. The limits of this article forbid entering upon details; only those cases can be alluded to in which morbid frequency or rarity of the pulse is the prominent, the most telling, symptom.

In many instances persistently rapid action of the heart may be ascribed to weakness of the heart (with dilatation ?), as in the so-called "irritable heart," due to either prolonged over-exertion or to sudden strain, as in lifting, running, rowing. In other cases it is clearly, or

* The name *Hemisystolie* was applied on the hypothesis that a normal systole of both ventricles was followed by a systole of the right ventricle alone. Sufficient evidence has not been brought to the support of this assumption. On the other hand, the occurrence of feeble systoles of the entire heart—so feeble that the left ventricle is not competent to open the aortic valves—is well known. Fick demonstrated such incomplete systoles as occurring in the morphine-narcosis of rabbits (Verhandlungen des V. Congr. f. innere Med., p. 97, 1886; and Riegel, *ibid.*, p. 101). Compare, also, Marey, Bull de l'acad. de méd, No. 42, 1883; Centralblatt f. klin. Med., No. 11, p. 181, 1884.

by exclusion, attributable to lesions of the cardiac nervous apparatus; the great frequency of the pulse in exophthalmic goitre is evidently of this character.

The name *tachycardia* (ταχύς, quick) has been applied to a class of cases in which an habitual high pulse-rate continues for a long period (in the absence of fever), interrupted or not by shorter paroxysms of an enormously accelerated action of the heart—a condition to which anæmic persons seem more predisposed than others. It occurs in the course of organic disease of the heart, or more often independently of it. In many instances it can be traced distinctly to lesions of the nervous system; among the anatomical lesions, those of the pneumogastric nerve, either central (in the medulla oblongata) or peripheral (compression by tumors or by cicatricial tissue*), offer the readiest physiological explanation. The affection may be accompanied by normal or by lowered tension; in the latter event the paralysis or paresis of the pneumogastric, or of the cardio-inhibitory centre, is associated with temporary paresis of the vaso-motor centre or fibres.[30] Tachycardia by irritation of the accelerating fibres in the sympathetic is less frequent, rarely of high degree, and more often paroxysmal than habitual. Theilhaber[31] reported a case caused by retroversion of the uterus—pulse, 200, temperature, normal; after reposition and retention of the womb by pessary, pulse, 80–90; after removal of the pessary, pulse, 110. Finally, tachycardia is caused by toxic agencies—coffee, tea, tobacco—and by gout. The paroxysms of extreme frequency may be excited by indigestion, flatulence, or any causes which ordinarily excite the heart's action.

In either form, the paroxysmal or the persistent, tachycardia may be accompanied by distressing symptoms, as palpitation, præcordial pain and anxiety, dyspnœa, feeling of "goneness," syncope, cold sweats; but even the palpitation is not always felt, and the amount of suffering is not always proportionate to the frequency of the pulse, sometimes, indeed, insignificant. The rate of pulsation may rise in the paroxysms to over 200, even over 300, as in the case of Bristowe, quoted by Broadbent.[32] Between the paroxysms, and in the habitual form, a rate as high as 164 has been observed. Of the two vagi, lesion of the left nerve seems to give rise to the greater acceleration. The tachycardia depending on structural lesion of the nervous apparatus is apt to be constant and of indefinite duration; the "neurotic" and toxic forms are more often paroxysmal. The paroxysms last from a few hours to several days; Dölger[33] relates a case in which the severe attack lasted seven days, Broadbent one in which for about three weeks "the pulse was never under 200, usually 240."

Less often do we meet with slow action of the heart as a consequence of morbid conditions. In its minor degrees the rare pulse is induced by morbid rise of blood-pressure; it is also caused by certain poisons, among them the bile-acids, whence the low pulse-rate sometimes found in jaundice. The rare pulse observed in some cerebral affections (*e.g.*, tubercular meningitis) may be due to anæmia or venous hyperæmia (more especially of the medulla oblongata) or to compression of the brain. Sudden slowing of a previously frequent pulse often announces a serious cerebral complication. In glosso-labial paralysis the pulse-rate has been found greatly diminished, probably from central excitation of the cardio-inhibitory fibres.

The higher grades of rare pulse—*p. rarissimus, bradycardia* (βραδύς, slow)—are usually connected with certain affections of the heart itself. Nauwerck[34] reported a case of inflammation of the parietal endocardium in a person sixty years old, with the pulse sometimes falling to 20 per minute. More often the highest degrees of bradycardia are connected with fatty heart, arteriosclerosis, and especially sclerosis and calcification of the coronary arteries, by means of their deleterious effect on the nutrition of the myocardium (?). Such cases abound in literature.[35] The pulse is usually anacrotic and very tardy.

FIG. 3199.—Female, aged Seventy-seven. Extensive Sclerosis of Coronary Arteries; Fatty Degeneration of Heart. Pulse-rate, 13 to 14. (Marey's.*)

It has been suggested that many of these cases are really heart-bigeminism, because sometimes the rate drops suddenly from, say, 60 to 30, and on improvement the bigeminous pulse appears as a transition to the normal rhythm and rate. But this is not the rule.

The connection between the structural disease of the heart and the lesion of innervation is not clear. Kisch[36] suggests, for the fatty heart of obese persons, that the lipæmia often found to exist in universal lipomatosis exerts the toxic effect of slowing the heart's action which has been obtained experimentally, in animals, by increasing the fats in the blood.

Concomitant symptoms, when present, are chiefly dyspnœa and præcordial anxiety, Cheyne-Stokes respiration, vertigo, syncope, and epileptiform seizures.[37] The epilepsy, in such cases, seems due to anæmia of the brain, closely related to the attacks of syncope which threaten the patient, especially when he assumes the upright position. Tripier,[38] on the contrary, thinks that epilepsy is the cause of the slow pulse; that hemisystoly, or heart-bigeminism, is always due to epilepsy, which is certainly too sweeping a conclusion;[39] the reverse relation seems to be the usual one.

THE CARDIOGRAM.—A graphic record of the impulse of the heart against the chest-wall can be obtained by means of sphygmographs constructed on the principle of Marey's; or by modifications of the same for their better application to the thorax, as Galabin's cardiograph; by transmission instruments, after the pattern of the cardiographs of Marey, Burdon-Sanderson, Meurisse et Mathieu, the compound sphygmograph of Keyt, and the pansphygmograph of Brondgeest. Less perfect tracings are made with Pond's and Dudgeon's sphygmographs.

The tracings of the apex-beat registered by these instruments are not as transparent in meaning as the sphygmogram, because they represent a greater complexity of movements, subject to more varying conditions, altered by the thickness and varying tension of the soft parts overlying the heart in the intercostal space, and apt

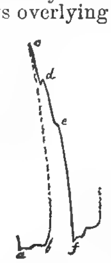

FIG. 3200.

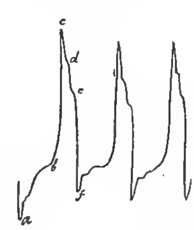

FIG. 3201.

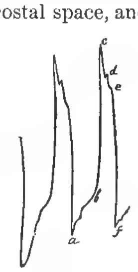

FIG. 3202.

FIG. 3200.—Normal Cardiogram. Pulse-rate, 81. (Sphygmograph of Marey (Breguet).)
FIGS. 3201, 3202.—Normal Cardiograms, after Landois. Pulse-rate, 74.2; respiration, 113.1. (Marey's sphygmograph.)

to be seriously confused by the simultaneous respiratory movements of the chest. Hence it may happen that only one or a few curves of a series give a complete and pure record of the heart's impulse. The latter is a rhyth-

* A case in point was observed by the writer, in which the right pneumogastric and sympathetic were both involved in a deep cicatrix in the neck, remaining after a very large and deep-seated abscess. The pulse-rate ranged from 110 to 140 and over for several months; pulse of low tension; general venous stasis (cyanosis), especially of the extremities and of the mucous membrane of the throat (from paresis of vaso-motor fibres in the cervical sympathetic?), more pronounced on the right side.

* This curve was taken several days before the death of a woman of seventy-seven years, who at the time suffered from great debility and had some spasms, chiefly of the muscles of the face and neck. The respiration was accelerated—26 and over. The pulse-rate on the previous day had been 10 per minute. Autopsy revealed a high degree of fatty degeneration of the heart and extensive atheroma of both coronary arteries, the left being very rigid and contracted, for nearly an inch almost impervious.

mical elevation and recession over the site of the apex, expressing the sum of the movements communicated to the chest-wall by the changing position, form, and consistency of that portion of the heart, and due to the contractions of the four chambers of the heart and to the closure of their valves. The normal cardiogram is the expression, therefore, of a considerable number of conditions, subject to great variations in themselves and disturbed by the acts of respiration. Nevertheless the apex-tracing of healthy persons is a characteristic curve, the details of which can be recognized in cardiograms of seemingly great disparity, and lend themselves in their main features to a comparatively simple interpretation.

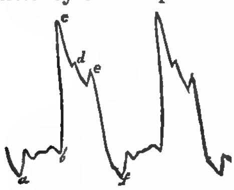

FIG. 3203.—Normal Cardiogram, after Galabin. Pulse-rate, 70. (Galabin's cardiograph.) (The lettering is altered to conform to that used in the present article.)

The lowest point in the normal cardiogram, a, marks the time when the ventricles have fully relaxed, and hence lies in the diastolic portion of the curve. From this point on (toward the right) we note a rise in the curve, more or less sudden, expressive of the filling of the ventricles, with one or more minor elevations produced by the contraction of the auricles. At the point b begins an abrupt and higher rise of the lever in obedience to the sudden contraction of the ventricles, and the termination of this rise forms the highest point, or apex, of the normal curve, c. The ventricles remain in systole for some time longer, during which the lever gradually falls to the point e. This portion of the curve is marked by two small elevations, d and e, which correspond to the closure of the aortic and pulmonary valves respectively.* The sudden relaxation of the ventricles now causes an abrupt fall of the lever from the point e to the lowest point of the curve, f (= a of the following curve). The palpable impulse of the heart coincides in time with the portion of the curve lying between b and e; the first sound of the heart is heard to begin at b; the second sound coincides with d and e. Landois has demonstrated that the aortic and pulmonary valves do not close exactly at the same time; but the interval between the two sounds produced is too short (.05 to .09 sec.) to be perceived by the ear, so that they are heard as one, while the elevations they start in the tracing are separate. It is only when the interval considerably exceeds the normal that the closure of the two sets of valves is revealed to the ear in separate sounds—*i.e.*, the second sound of the heart is "reduplicated."† The cause of the interval is the difference in blood-pressure in the aortic and pulmonary systems; that in the aorta, being much greater, leads to an earlier recoil, even though both ventricles complete their systole and relax at the same time.

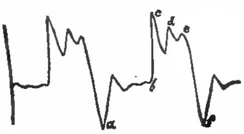

FIG. 3204.—Normal Cardiogram, after Keyt. Pulse-rate, 72. (Keyts' compound sphygmograph.) (Lettering altered.)

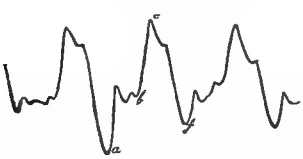

FIG. 3205.—Normal Cardiogram. Pulse-rate. 66. (Dudgeon's sphygmograph.)

The line $b\ e$ may be called the systolic portion of the curve; the line from e to the point b of the next curve, $e\ f + a\ b$, the diastolic portion, consisting of the pause and the auricular systole. The period $b\ e$ (between the first and second sounds) commonly measures about two-fifths of the entire cardiac revolution. Keyt found, as an average of twenty measurements, with a mean frequency of 74.7, or a pulse-length of .8075 sec., the systole = .3269 sec., the diastole = .4806 sec. With less frequent beats the diastole becomes longer, with greater frequency shorter, while the systole may vary in either direction.*

In the cardiogram taken while respiration is performed, the individual curves of the series are of very different height, and their details are not nearly so uniform as those of the sphygmographic tracing, owing to the disturbing influence of the respiratory movements of the chest-wall. At the height of an inspiration, owing to the interposition of the borders of the lung, the apex-beat becomes less visible and less distinct to palpation than during expiration, and deep respiration increases these differences; in shallow respiration they may escape detection by the hand or finger, but they are still perceptible in the cardiogram. (Compare Figs. 3208, 3209.) This (normal) behavior of the tracing presupposes that the anterior border of the left lung is intact and making its normal excursions. Adhesive inflammation, which fixes the left lung so that its border does not cover the cardiac apex during inspiration, is apt to reverse the differences in the curves in such wise that the higher phases of the cardiogram correspond to inspiration, the low curves to expiration, because during inspiration the intra-ventricular pressure rises.[43]

Pathological.—In cases of heart disease the tracings of the cardiograph may contribute to our appreciation of the details of the heart's action, and hence to diagnosis. Much has yet to be learned in this direction. In individual cases our knowledge may be further enhanced by tracings taken at other points than the site of the apex—*e.g.*, in or toward the second left intercostal space to demonstrate increased tension in the pulmonary artery (accentuation of the pulmonary second sound), or over areas in which a systolic retraction of the chest-wall is visible, where the tracing will be in a sense "negative:" the systolic ascent will be converted into a descent, and *vice versâ*, while the secondary (valvular) elevations will remain positive.

Pathological apex-curves exhibit enormous differences in height. In hypertrophy with dilatation the excursions of the lever of a Marey's sphygmograph often amount to several inches. In atrophy or degeneration of the heart's muscle the tracings become so tiny as to lose all detail and character, or vanish altogether. (It must be remembered that in some cases—as when the apex beats against a rib, or in violent dyspnœa—intelligible tracings cannot be obtained at all.) The effect of simple hypertrophy is mainly a broadening of the summit of the curve, owing to forcible systole and early closure of the valves (recorded by waves placed high up, near the apex, before the lever has descended much). Dilatation with hypertrophy tends to produce curves of great magnitude, the apex very high and pointed, followed by a considerable fall of the lever before the valves close, as in Fig. 3206. The size of car-

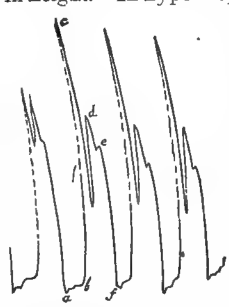

FIG. 3206.—Hypertrophy and Dilatation of Left Ventricle in a Case of Aneurism of the Thoracic Aorta. Pulse-rate, 90. (Marey's sphygmograph.)

* According to the interpretation of Landois. More accurately, I think, the moment of closure of the valves is represented by the notches preceding the waves d and e.

† In a case of phthisis (chronic pneumonia with cavities, fatty degeneration of right heart, chronic interstitial nephritis) without valvular lesions, in which the second sound was very distinctly reduplicated, Maurer (Deutsches Arch. f. klin. Med., 1879, Bd. 24) measured the interval between d and e = .156 sec., while in a number of normal cardiograms he found it to equal only .092 sec.

* The interpretation here given of the details of the cardiogram is that of (Marey and) Landois, adopted by many cardiographers,[40] especially German and French. Some English authors (*e.g.*, Bramwell) still follow the labored interpretation of Garrod,[41] or the equally artificial one of Galabin,[42] who places the beginning of the systole in about the middle of the up-stroke, where he recognizes a small rise (in some of his curves) as the expression of the closure of the auriculo-ventricular valves, and the end of the systole at the foot of, or at some point in, the main descent (between e and f), where he sometimes finds a small notch as the indication of the closing of the aortic valves. The waves in the plateau (from c to e) are explained (d) as due to "recoil toward the apex of the blood, which had been forcibly impelled against the auriculo-ventricular valves at the moment of their closure," and (e) to "locomotion of the heart as a whole," or "to the jerking forward of the apex at the end of systole." Keyt divides the curve into systolic and diastolic portions at exactly the same points as Landois, but recognizes no indication of valve-action, and explains the elevations of the systolic portion by variations in blood-pressure and muscle-contraction of the ventricles.

diographic curves must be studied with reference to the frequency and rhythm of the beat.

The auricular portion of the curve, *a b*, is well developed in proportion to the systolic elevation in cases of hypertrophy and overaction of the auricles, abrupt rise and increased height of the first denoting great force of auricular contraction. When the auricle is both large and strong, the curve may rise suddenly into a sharp peak, with a quick descent down to the point *b*, as in Figs. 3207 and 3208. Rough presystolic murmur—the purring thrill of mitral stenosis—is often pictured in this portion of the curve as a serrated line. (Compare Fig. 3212.)

FIG. 3207.—Valvular Lesions; Mitral Regurgitation Predominating. (Marey's sphygmograph.) (The first curve is very imperfectly reproduced, but both show plainly the violent auricular systole.)

The height of the ventricular upstroke, *b c*, is proportioned to the distinctness of the apex-impulse. It is invariably great in excentric hypertrophy of the left ventricle, especially so in aortic valvular disease and in combined lesions in which aortic insufficiency predominates. (Compare Figs. 3206, 3213.) The apex in such cases is apt to be very sharp, the first descent from it, abrupt.

The valvular elevations in the descent, or following the apex, indicate the tension in the aortic and pulmonary systems. Increased height of the elevations *d* and *e* denote, not only high tension in the respective vessel, but also testify to its elasticity and tone. When the latter properties are impaired by long-continued high pressure, dilatation, or atheromatous change, these waves are delayed and small. In some cases the rise of tension in the pulmonary artery, of which increased loudness of the

FIG. 3208.—Mitral Regurgitation. (Marey's sphygmograph.)

pulmonary second sound gives evidence, is well shown in the cardiogram by an earlier and higher wave, *e*, sometimes an early sign in mitral disease; if the blood-pressure in the aorta is lowered at the same time, *d* may be so far delayed that the two elevations *d* and *e* are merged into one, as in Fig. 3208.

Diseases of the right heart and obstruction of the pulmonary circulation affect the cardiogram only by the al-

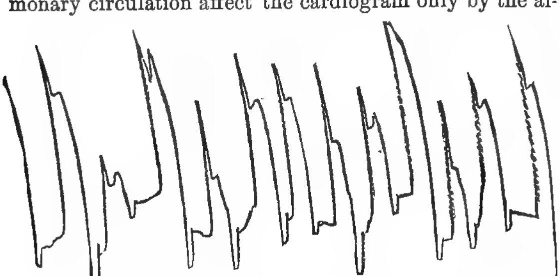

FIG. 3209.—Mitral Regurgitation. (Marey's sphygmograph.)

tered size and force of the right chambers, as above mentioned, and by the altered tension in the pulmonary artery. Valvular disease of the left heart is often expressed in more characteristic changes.

Mitral Regurgitation commonly shows a marked auricular portion, *a b*, as in Figs. 3207, 3208, 3210, owing to dilatation and energetic systole of the left auricle; a small aortic wave, *d*, on account of the lowered tension in the aorta, and a large and higher-placed pulmonary wave, *e*, as in Fig. 3210, on account of the increased tension in the pulmonary artery (loud second sound); the latter wave may be enlarged and hastened so much that it coalesces with the aortic wave, as in Figs. 3208 and 3209. The height of the whole curve is proportioned to the degree of enlargement of the heart. Comparing the cardiogram with the simultaneous sphygmogram (on polygraph or Keyt's sphygmograph), the presphygmic interval is found abnormally long.

FIG. 3210.—Mitral Insufficiency, after Maurer. (Marey's cardiograph.)

In *Mitral Stenosis* the auricular portion is lengthened (*i.e.*, of longer duration), and its tracing is higher, because the left auricle is dilated, contracts with force, and

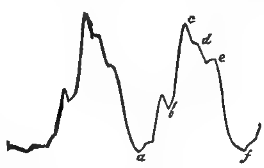

FIG. 3211.

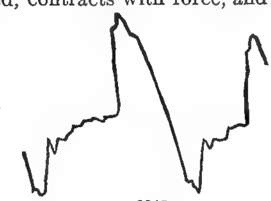

FIG. 3212.

FIG. 3211.—Mitral Stenosis, after Galabin. Pulse-rate, 80. (Galabin's cardiograph.)

FIG. 3212.—Mitral Stenosis (long, rough, presystolic murmur), after Galabin. Pulse-rate, 57. (Galabin's cardiograph.)

empties itself with difficulty; it often bears a series of wavelets, giving it a serrated appearance, corresponding to the purring thrill felt by the hand. In the systolic portion the increased blood-pressure in the pulmonary artery makes the wave *e* conspicuous. In case of reduplication of the second sound, the waves *d* and *e* are separated by a longer interval; Ott and Haas[43] attribute the late closure of the pulmonary valves to the diminished elasticity of the artery in consequence of long-continued high pressure in it.

Aortic Incompetency alters the apex-tracing chiefly through the factors of dilatation and hypertrophy of the left ventricle; the curve is very high, its apex pointed, the descent sudden; the pulmonary elevation is apt to be conspicuous, higher than the aortic elevation, sometimes, indeed, enormous, as in Fig. 3214, which reproduces a tracing taken, not at the apex, but nearer the pulmonary area. The auricular portion of the cardiogram is not changed in pure aortic insufficiency; sometimes its second wave (near *b*) becomes very distinct, as in Fig. 3214. In free regurgitation the presphygmic interval is shortened; the radial pulse follows so quickly upon the car-

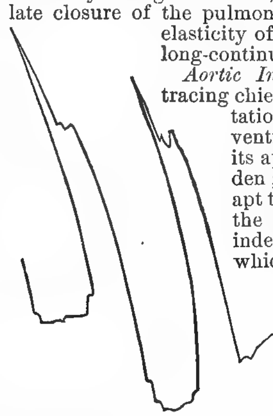

FIG. 3213.—Aortic Insufficiency, after Maurer. (Marey's sphygmograph.)

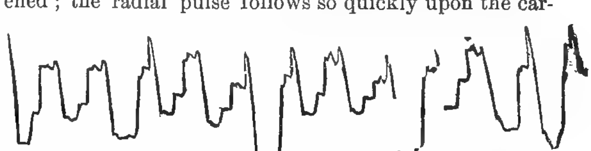

FIG. 3214.—Aortic Regurgitation; Great Dyspnœa. (Tracing taken in fifth intercostal space, one and one-half inch inside of apex-beat.) (Marey's sphygmograph.)

diac impulse that this phenomenon becomes a valuable diagnostic sign.

Aortic Stenosis is said to make the primary ascent small and slow (sloping), and the plateau of the systolic portion large, sometimes rising toward the end of the systole, sometimes, also, marked by irregular denticulation, answering to the harsh systolic murmur (Landois). The total systole is abnormally long.

BIBLIOGRAPHY.—From the immense literature on the subjects treated of in this article, it is possible only to refer to the larger physiological treatises; to the fundamental works of E. H. Weber (1827–52); Volkmann ("Hæmodynamik," 1850); Vierordt ("Lehre vom Arterienpuls," 1855, *et al.*); Valentin ("Versuch einer physiol. Pathologie des Herzens u. d. Blutgefässe," 1866); Marey ("Physiologie méd. de la circulation du sang," 1863; "Du mouvement dans les fonctions de la vie," 1867; "Travaux du laboratoire," 1876; "La méthode graphique," 1878); O. J. B. Wolff ("Charakteristik des Arterienpulses," 1865); Rive ("De sphygmograaf en de sphygmogr. Curve," 1866), Burdon-Sanderson ("Handbook of the Sphygmograph," 1867, *et al.*); Landois ("Die Lehre vom Arterienpuls," 1872; "Graphische Untersuch. über den Herzschlag," 1876); Moens ("Die Pulscurve," 1878); Keyt (*op. cit. infra*); and to the manifold labors of Mach, Czermak, Anstie, B. F. Foster, Mahomed, Garrod, Galabin, Roy, Broadbent, Fick, Brondgeest, Mosso, François-Frank, Waldenburg, Sommerbrodt, Riegel, Grunmach, v. Basch, G. v. Liebig, and many others.

PULSE, VENOUS. In peripheric veins a pulsation has been observed, in exceptional cases, which is simply the arterial pulse carried forward through the capillaries into the veins. A necessary condition for this pulsation is, probably, wide dilatation of the minute arteries of the part, either by active vaso-dilatation (as in the case of the secreting salivary gland) or by paralysis. In a more limited and stricter sense, the name "venous pulse" refers to pulse-movements occurring in the large veins near the heart, especially the jugular veins, both in health and in disease.

1. NORMAL.—Pulsation of the jugular veins has long been known as a pathological phenomenon, but the demonstration of a venous pulse in health is of recent date. Potain,[1] in 1867, published a sphygmogram of a jugular pulse from a person in health. Mosso[2] showed that there is a physiological pulse in the jugular veins which can often be observed in healthy persons, and that this normal venous pulse is negative, *i.e.*, the reverse of an arterial pulse. Riegel[3] and Gottwalt[4] further proved that a jugular pulse is a constant normal phenomenon in dogs and rabbits; the same pulsation can be observed in many other veins, especially in the territory of the inferior vena cava. The older clinicians who had met with this jugular pulse in man, in the absence of valvular disease of the heart, had not been able to explain it without assuming an insufficiency of the valves of the jugular veins. Mosso, first showing the negative character of it, connected it with the "negative pulse of the thorax." Riegel explains it in the simplest manner by the varying velocity with which the blood of the jugular veins flows into the right auricle during the different phases of the heart's movements. It is approximately an inverse arterial pulse, making a descent synchronous with the cardiac systole, an ascent with the ventricular diastole and auricular systole. When the ventricle contracts (auricular diastole), the flow of venous blood is accelerated, causing a systolic venous collapse; but during the diastole of the ventricle, and especially during the auricular systole, the venous flow is retarded, causing a diastolic swelling of the jugular veins. Obviously, this process does not require for its consummation an insufficiency of the venous valves.

Graphic reproduction of this pulse shows a curve the ascent of which is commonly interrupted by a wave, while the descent is uninterrupted; the curve is "anadicrotic, catamonocrotic." The first part of the ascent corresponds to the diastole of the ventricle, the second ascent to the systole of the auricle, the descent to the systole of the ventricle.

2. PATHOLOGICAL.—The jugular pulse seen in heart disease is of different character and origin. Contrary to the normal negative venous pulse, it is a positive one, *i.e.*, its ascent is synchronous with the cardiac systole; and it depends upon a centrifugal movement, a regurgitation of the blood. This can occur only when the tricuspid valve is insufficient, and therefore it is a pathognomonic sign of tricuspid regurgitation—whether the insufficiency be due to inflammatory disease of the tricuspid, or to dilatation of the right heart consequent on disease of other valves. This pulsation may be confined to the lower portion of the vein, below the first set of venous valves; but when the vein is distended and (or) its valves are incompetent, the positive jugular pulse extends higher up into the vein. The regurgitation extends into the hepatic veins also, where it causes throbbing or pulsation of the liver synchronous with the cardiac impulse. Whenever the phenomenon is well developed it is not only distinctly visible, especially in the right external jugular, but equally palpable and accessible to the sphygmograph, sometimes yielding a tracing of great amplitude. Yet neither does the venous pulse occur in all cases of tricuspid insufficiency, nor is the amplitude of the pulse-wave in the jugular vein an indication of the degree of the valvular defect. The form of the sphygmographic curve is similar to that of the negative pulse, anadicrotic. *The criterion of the venous pulse of tricuspid insufficiency is the time of its occurrence; it is systolic. The normal venous pulse is presystolic* (Riegel).

The latter is sometimes—in cases of over-distention of the right heart, but with competent tricuspid valves—exaggerated, and is then visible as a presystolic swelling of the jugular bulbus. Confounding this *presystolic jugular pulse* with the systolic venous pulse of tricuspid regurgitation has caused much difficulty of interpretation and much confusion on the subject.

Absence of venous pulse in the presence of extreme

venous congestion has been held [5] diagnostic of tricuspid stenosis.

PUMPKIN-SEED (*Pepo*, U. S. Ph.). The seed of *Cucurbita pepo* Linn., order *Cucurbitaceæ*, the common Pumpkin; a vine scarcely known in the wild state, but probably of Asiatic origin. It has been cultivated from time immemorial for its edible fruits. Its seeds, as well as those of other species—gourds, squashes, and cucumbers—have long been considered to have medical properties (*les grosses et les petites semences froides*), but their present employment as tænicides is of rather modern origin.

The seeds of several species and of numerous varieties of pumpkins, squashes, etc., are very similar in appearance, and are probably supplied in the market somewhat indiscriminately; the officinal description will serve to eliminate some of them: "About three-quarters of an inch (two centimetres) long, broadly ovate, flat, white or whitish, nearly smooth, with a shallow groove parallel to the edge; containing a short, conical radicle and two flat cotyledons; inodorous, bland, and oily." The testa is tough and flexible, and must be removed when the seed is prepared for use; the embryo is exalbuminous and has a pleasant, nutty, sweetish, oily taste.

Pumpkin-seed, besides *sugar, mucilage, albuminous substances, ferments*, and *asparagin*, contains twenty-five or thirty per cent. of a pale yellow, thickish, almost non-drying, odorless, and tasteless *fixed oil*, composed of glycerides of *oleic, palmitic, myristic*, etc., *acids*, and some free acids. The medicinal power is contained in the oil, but has never been separated.

USE.—This seed is a moderately efficient, agreeable, and entirely safe agent for the destruction of tape-worms. It should be preceded by the usual preparatory fasting (see Koosso), and be followed by a cathartic. It is not quite so certain as koosso and pelletierine, but is much less disagreeable than the former. Pumpkin-seed appears to vary considerably in its activity, probably in consequence of coming from different varieties or different conditions of cultivation. That of the West Indies and other southern countries is probably the best.

The usual method of administration is as an emulsion, made by pounding and rubbing the peeled kernels in water; from thirty to fifty grammes (before peeling) is the usual dose. The oil, if attainable, would no doubt be a better form.

PUNTA RASA, FLA. The accompanying chart, obtained from the Chief Signal Office, at Washington, represents the climatic conditions observed at Punta Rasa, a little hamlet situated near the mouth of the Caloosahatchee River, on the Gulf coast of Florida, about one hundred and seventy miles S.S.E. of Cedar Keys, and one hundred and twenty miles N. of Key West. As may be seen by carefully comparing the charts for these three

places, the winter climate at Punta Rasa is in character intermediate between that of Cedar Keys and that of Key West, except that, in respect to the humidity of its atmosphere, it is drier than either of the other places. The temperature of the sea-water at Punta Rasa is such as to admit of sea-bathing all the year round. As a winter health-resort, Punta Rasa appears to be as yet but little developed; under proper management and with intelligent sanitary supervision, it is likely to become a useful and favorite resort for such as require a very decidedly mild winter climate. (See article Florida, in vol. iii. of this HANDBOOK; and also Dr. J. C. Wilson's "Remarks upon the Climate of Florida," read before the American Climatological Association in 1885, and published in the *New York Medical Journal* for December 19th of that year.) *H. R.*

PURGATIVES, OR CATHARTICS, are medicines which are used to produce alvine evacuations. According to their activity and power, they are divided into laxatives and mild and drastic purgatives.

Purgatives which act very gently, producing soft, feculent stools without notable irritation, are called *laxatives.* This term is also applied to more powerful purgatives when they are given in small doses, so as to act mildly (see Laxatives, vol. iv., p. 458.)

Purgatives which operate briskly, usually producing more or less fluid evacuations, sometimes with griping and tenesmus, but without serious irritation, are called *mild* or *simple purgatives.* To this group belong some of the salts of magnesium, sodium, and potassium, which, from their resemblance in chemical and physical properties, and in physiological action, are termed *saline* purgatives.

The term *drastic* is applied to those purgatives which operate energetically, producing numerous evacuations, and, in excessive doses, more or less gastro-intestinal irritation.

Purgatives which produce watery stools, especially the salines and some of the drastics, are called *hydragogues*, and those which cause the evacuation of large quantities of bile, *cholagogues.*

MODE OF ACTION.—All purgatives accelerate the peristaltic movements of the intestines. Radziejewsky carefully observed the rapidity of peristalsis in dogs, both before and after the administration of purgatives. In the normal state the movements of the small intestine were rapid, those of the large intestine very slow. After the administration of purgatives, the movements of both became much accelerated, but most markedly those of the large intestine.

It was assumed that purgatives especially the hydragogues, also induce a discharge of fluid from the intestinal mucous membrane. Experiments on animals at first seemed to show that this was an error. Thiry completely separated a portion of the small intestine from the rest of the bowel, without dividing its vessels and nerves, sewed up one end, which was returned into the abdominal cavity, and attached the open end to the wound in the abdominal wall. Into the cul-de-sac thus formed he introduced croton-oil, senna, and Epsom salt. No accumulation of fluid took place. Schiff experimented in a similar manner with aloes, jalap, and sulphate of sodium, and Radziejewsky with croton-oil and sulphate of magnesium, both with the same negative result. Radziejewsky also analyzed the fæces before and after the administration of purgatives. The evacuations produced by purgatives contained more water and sodium salts than normal fæces, and sometimes products of pancreatic digestion, but never as much albumen as should have been present if transudation of fluid from the intestinal blood-vessels had taken place. It was therefore concluded by these investigators, and is still maintained by some recent authors, that purgatives do not induce either transudation or increased secretion, and that the watery character of the stools results only from the greatly accelerated peristalsis, which interferes with the absorption of the fluid normally secreted.

But subsequent investigations yielded different results. Moreau introduced sulphate of magnesium into a portion of intestine isolated by means of two ligatures, and after some hours found a decided accumulation of fluid. Brunton, experimenting in a similar manner, found that croton-oil, gamboge, elaterin, and Epsom salt caused a decided accumulation of fluid. That the accumulated fluid was not a transudation was evident from the fact that it contained very little albumen. Brieger injected into an isolated portion of intestine very small quantities of colocynth. No accumulation of fluid took place, but the bowel was contracted and slightly reddened. Larger quantities of colocynth, as well as croton-oil, caused an accumulation of bloody fluid, with decided inflammation of the mucous membrane. After injecting calomel, senna, rhubarb, aloes, and castor-oil, Brieger found the bowel empty and firmly contracted. Sulphate of magnesium in very dilute solution caused no accumulation of fluid, but concentrated solutions of this salt, so also Glauber salt, caused very decided accumulation. That the fluid was a secretion, and not a transudation, was evident from the fact that it readily converted starch into sugar and dissolved raw fibrin.

Thus it has been found in experiments that sulphate of magnesium, sulphate of sodium, croton-oil, gamboge, colocynth, and elaterin, not only accelerate the peristaltic movements of the intestines, but also induce a secretion of watery fluid from the intestinal mucous membrane; and that castor-oil, rhubarb, aloes, senna, calomel, and minute quantities of colocynth accelerate peristalsis, but do not notably increase secretion.

Hess, in experiments on dogs, endeavored to determine the manner in which purgatives increase the peristaltic contractions. He made gastric fistulæ a short distance from the pylorus, so that he could easily introduce purgatives into the duodenum. After having determined the quantity of the purgative (sulphate of sodium, castor-oil, croton-oil, senna, colocynth, gamboge, and calomel) which would act briskly, he introduced into the duodenum a small, empty india-rubber balloon, to which was attached a long, fine india-rubber tube. After this had been carried by the normal peristaltic contractions a certain distance, which varied in the different experiments, he filled it with water to such a degree as to obstruct the bowel. The purgatives which previously had acted briskly then completely failed. Hess therefore concluded that the peristaltic movements excited by purgatives are probably not propagated through long distances by means of nervous apparatus, or, according to Engelmann, from muscle to muscle, but that they are reflexly excited in each part of the intestine by direct stimulation of its mucous membrane.

MILD PURGATIVES.—Of the purgatives which act vigorously, without causing severe irritation of the intestines, the following are commonly employed: aloes, rhubarb, senna, castor-oil, salines, and mercurials.

Aloes.—In large doses, from five to twenty grains, aloes produces semiliquid or liquid stools. The first evacuation rarely occurs before six hours, and often not before ten or twelve hours. Some griping usually precedes the evacuations, and they are often attended by a feeling of heat in the anus, and by straining, especially if the medicine be repeatedly taken. From the slow action and the tenesmus, it is supposed that aloes influences the rectum more than other parts of the intestines.

In experiments on rabbits, Kohn found that aloes caused moderate hyperæmia of the stomach, intestines, and kidneys. In various animals large doses of aloin, injected into the subcutaneous tissue, were followed by gastritis, sometimes with hæmorrhage and ulceration, and in dogs and rabbits by degeneration of the epithelium of the kidneys.

According to the experiments of Rutherford, aloes increases the secretion of bile, and renders it more watery. Various observers have found that it does not act when bile is absent from the intestines.

Aloes was formerly employed in large doses to produce brisk purgation, when acute disorder of any organ of the body supervened soon after the cessation of an habitual hæmorrhoidal discharge. It was sometimes

given to produce a revulsive effect in cases of congestion of the brain, apoplexy, hemiplegia, and insanity. At the present time it is rarely used, except in small doses as a laxative. According to G. B. Wood, it sometimes quickly cures jaundice when other remedies have failed.

Aloes is contra-indicated in inflammatory affections of the intestines and kidneys, in irritable and bleeding piles, in uterine hæmorrhage, and during menstruation.

It is generally administered in pillular form, and the officinal *pills of aloes* are preferable to other preparations. Each pill contains two grains of aloes.

Rheum.—In doses of thirty to forty grains, taken at once, or ten to twenty grains, repeated several times at short intervals, rhubarb produces semiliquid stools in from five to ten hours, usually with griping, but without severe irritation. Some constipation generally follows. Recent experiments have confirmed the ancient opinion that rhubarb increases the secretion of bile.

Rhubarb is a suitable purgative when the bowels require thorough evacuation in patients who are occasionally subject to diarrhœa. Sometimes it is preferred to other purgatives in catarrhal jaundice.

It may be given in the form of powder, fluid extract, tincture, or wine. Aromatics are generally associated with it to prevent its griping effect. ℞. Pulv. rhei, ℈ij.; pulv. aromatici, ℈j. M. Div. in pulv. iv. Sig.: One powder every two hours. They may be conveniently taken in syrup or molasses, or in wafers. The fluid extract is given in doses of fifteen to thirty minims, mixed with syrup and an aromatic water. ℞. Extr. rhei fluid., ʒ jss.; syr. zingiberis, ℥ ss.; aq. cinnam., ℥ jss. M. Sig.: One tablespoonful every two hours till the bowels move. The tincture and wine are suitable for feeble patients, especially if they are accustomed to alcoholic beverages, and may be given in doses of half an ounce, repeated, if necessary, at convenient intervals.

Senna.—Senna operates gently and slowly in doses of fifteen to thirty grains, producing one or two pultaceous stools in from five to ten hours. Large doses act more briskly. Two or three drachms usually produce semifluid discharges in three or four hours. The evacuations are preceded by pretty severe tormina, and sometimes by nausea and eructations. Borborygmi and occasional small fluid stools often continue for from twelve to twenty-four hours.

Though it acts vigorously, and produces quite liquid stools, containing about eighty-five per cent. of water, senna never causes severe irritation or inflammation of the intestines. It is supposed, however, that large doses may influence the uterus, and, given during pregnancy, induce hæmorrhage and abortion.

The watery character of senna stools is generally regarded as evidence of increased intestinal secretion; but in careful experiments Brieger found no accumulation of fluid in an isolated loop of intestine with which senna had been in contact some hours. That it greatly accelerates the peristaltic contractions of the small intestine appears from Radziejewsky's experiments. This investigator found that in dogs, normally, from seven to nine discharges took place from a fistula in the ascending colon in three or four hours after a feeding; but when senna was administered the discharges began in ten or fifteen minutes, and numbered about thirty in four hours.

Cathartic acid, the active principle of senna, in doses of two to five grains, produces thin stools with colicky pains in from three to fourteen hours. Two grains, injected into the subcutaneous tissue, were followed by copious evacuations in from eight to twelve hours.

As senna acts rapidly and efficiently, it is suitable when the contents of the intestines require speedy removal. Combined with Epsom salt, as in the officinal compound infusion of senna, it is frequently employed in the early stage of inflammatory diseases, except those of the alimentary canal. It is better adapted than rhubarb and some other mild purgatives for patients disposed to costiveness.

Senna, in large doses, is contra-indicated in inflammation of the intestines, hæmorrhoids, menorrhagia, threatening abortion, and prolapse of the uterus or rectum.

It is generally given in the form of the *infusum sennæ compositum*, which, in quantities of about two ounces, repeated several times at intervals of one or two hours, soon produces copious watery discharges. The fluid extract of senna may be given in doses of half a drachm to two drachms with syrup and an aromatic water. ℞. Extr. sennæ fluid., ℥ ss.; syr. zingiber., ℥ ss.; aq. cinnam., ℥ iij. M. Sig.. A tablespoonful every hour until the bowels act. The syrup of senna is a convenient preparation for children in doses of one to four drachms.

Oleum Ricini.—Castor-oil, in doses of half an ounce to an ounce, usually produces semifluid evacuations in from three to six hours, generally with little or no griping or other symptoms indicating irritation of the intestines. Nausea and vomiting may occur in very susceptible persons, especially if the oil is rancid or the stomach disordered.

From its efficient and speedy operation, castor-oil is well adapted to all cases requiring a thorough cleansing of the alimentary canal, as when the presence of poisons, undigested food, or products of decomposition in the intestines indicates the use of a brisk purgative. Its gentle, unirritating action renders it suitable when a purgative is required in inflammation of the intestines, inflamed hæmorrhoids, fissure of the anus, metrorrhagia, and after parturition. For methods of disguising its taste, see vol. iv., p. 459.

Saline Purgatives.—The following saline purgatives are commonly employed: Sulphate of magnesium, sulphate of sodium, citrate of magnesium, tartrate of potassium and sodium, and bitartrate of potassium.

Large doses of saline purgatives produce copious watery stools. This peculiar action was explained by chemists as resulting from osmosis, the dense saline solutions within the intestines causing the less dense fluid of the blood to pass through the walls of the blood-vessels. But the fact that large doses of salines, when given in very dilute solution, so as to be less dense than the fluid of the blood, act as efficiently and often more speedily than concentrated solutions proved that this theory was untenable. Subsequently it was shown, by Buchheim and others, that only salts of low diffusibility are efficient purgatives, and that this property impedes their absorption in the intestines, causing them to pass nearly entire into the lower part of the large bowel and to excite purgation.

For a time it was supposed that the accelerated peristalsis resulting from the presence of saline solutions was sufficient to explain their rapid and peculiar action. But the investigations of Moreau, Brunton, Brieger, Hay, and others, have conclusively shown that dense saline solutions produce an active secretion of watery fluid from the intestinal mucous membrane. Brieger and Hay found that very dilute solutions, although they may purge rapidly, do not cause an increase of secretion; and Hay observed that when concentrated solutions are given, the quantity of fluid secreted depends upon the degree of concentration. Solutions containing less than five per cent. of a salt, produce little or no secretion, but stronger solutions always have this effect. Under ordinary circumstances, the amount of fluid secreted corresponds very nearly to the quantity required to form a five per cent. solution of the amount of salt administered. In consequence of the secretion of a large quantity of fluid, when concentrated saline solutions are given, the fluid of the blood becomes proportionately diminished. This continues only a short time, as the blood absorbs fluid from the tissues until it has nearly regained the quantity lost by increased secretion.

Thus the mode of action of saline purgatives depends upon the quantity administered and the degree of dilution. Very dilute solutions excite no intestinal secretion, but rapidly produce watery stools; while concentrated solutions cause a decided increase of secretion, diminish the fluid of the blood, excite absorption of fluid from the tissues, and in a short time produce watery evacuations.

Saline purgatives are preferred to other mild cathartics to evacuate inspissated fæcal masses. As a rule, they should be given in very dilute solution. In the early stage of inflammatory diseases, salines are often employed for the purpose of lowering temperature and blood-pressure, and thus diminishing the inflammation. They are of little use in such cases unless given in concentrated solution, so as to excite a decided increase of the intestinal secretion. The utility of salines is most conspicuous in cases of ascites and general dropsy. Administered in very concentrated solution, they often in a short time produce a very notable effect, especially if the patient have entirely abstained from food and drink for some hours before taking the saline.

Magnesii Sulphas.—Epsom salt is generally preferred to other saline purgatives. In doses of half an ounce to an ounce it usually produces watery stools in several hours, the first discharge sometimes taking place in one hour. This rapid action is rarely attended by severe griping. As it is readily soluble in water, it may be given in very concentrated solution, a method strongly recommended by Hay in cases of dropsy. It is frequently associated with senna, as in the compound infusion of senna.

Its taste is somewhat improved and its activity increased by sulphuric acid. ℞. Magnesii sulph., ℥ j.; aq. destill., ℥ ij.; acid. sulph. arom., ʒ ss.; syrupi., ℥ j. M. Sig.: One or two tablespoonfuls every hour. The bitterness of Epsom salt may be disguised by strong coffee and aromatics, especially cinnamon-water. ℞. Magn. sulph., ℥ j.; aq. cinnam., ℥ iij.; syr. aurant., ℥ j. M. Sig.: A tablespoonful every hour.

Sodii Sulphas.—Glauber salt has a still more repulsive taste than Epsom salt. It is therefore rarely employed when saline purgatives are indicated. According to recent researches, it causes a decided increase of the secretion of bile and renders it more watery. In all other respects its action closely resembles that of Epsom salt. The following substances have been employed to correct its disagreeable taste: Lemon-juice, aromatic sulphuric acid, carbonated water flavored with syrup, and extract or fluid extract of licorice.

Sulphate of sodium is the principal constituent of Carlsbad water and of the Carlsbad salt of commerce. According to W. Jaworski ("Ueber Wirkung, therapeutischen Werth und Gebrauch des neuen Karlsbader Quellsalzes," Wien, 1886), the natural Carlsbad *Quellsalz* contains from 46 to 47.5 per cent. of sulphate of sodium, from 33.5 to 36 per cent. of bicarbonate of sodium, and from 16 to 17 per cent. of chloride of sodium.

Carlsbad water has been found useful in catarrhal affections of the alimentary canal, habitual constipation, catarrhal jaundice, inspissation of bile and gall-stones, fatty liver, cirrhosis of the liver, and excessive obesity.

According to Jaworski, the natural Carlsbad *Quellsalz* is most advantageously employed as follows: It should be taken in the morning, immediately after rising, in sufficient water to form a two per cent. solution. The dose of the salt may vary from five to fifteen grammes (ʒ j.–iv.). As an occasional purgative the dose is ten grammes (ʒ ijss.), which should be taken in cold water or soda-water. Used methodically in habitual constipation, the dose should not exceed ten grammes, and should generally be less, and be taken in cold water. In catarrhal jaundice, from ten to fifteen grammes, dissolved in warm water (30° to 40° C.), should be taken daily for at least two weeks.

Liquor Magnesii Citratis.—The solution of citrate of magnesium has an agreeable taste, and is therefore often preferred to other saline purgatives to unload the bowels in simple constipation. It is, however, less efficient than the sulphates of magnesium and sodium, sometimes operating briskly, sometimes producing no purgative effect. Usually a whole bottle, containing twelve ounces, taken in several portions at short intervals, is required. In cases of dropsy and inflammatory diseases other saline purgatives are preferable.

Potassii et Sodii Tartras.—In doses of half an ounce to an ounce, Rochelle salt usually produces liquid stools in a few hours. As it has a less disagreeable taste than Epsom salt, generally agrees well with the stomach, and acts gently, it is often employed when a mild purgative is indicated in the diseases of children, females, and delicate persons. It somewhat increases the secretion of bile. From two to four drachms, dissolved in sweetened water, may be taken at intervals of two hours till the bowels respond.

Potassii Bitartras.—Large doses of cream of tartar, half an ounce to an ounce, are followed by watery stools, which are often preceded by flatulence and griping. It is rarely used alone, but frequently in combination with jalap. When given in large doses, it should be suspended in an aromatic water to prevent griping.

Mercurial Purgatives.—Of the preparations of mercury which produce catharsis, calomel and blue mass are frequently used. Metallic mercury is sometimes employed in obstruction of the bowels.

Hydrargyri Chloridum Mite.—Calomel, in doses of from five to ten grains, usually acts in about six or eight hours, producing copious semiliquid, dark-brown or green evacuations. As a rule, no marked incidental effects are observed; but sometimes, especially after the larger quantity, the evacuations are preceded by griping, nausea, and depression. Smaller doses, one to three grains, act slower and very gently. Accurate chemical analyses have discovered in calomel stools bile-pigments, leucine, tyrosine, peptones, sulphide of mercury, and unchanged calomel, but no scatol and indol.

The presence of bile in the stools was formerly regarded as a certain evidence of an increased secretion of bile. But in numerous careful experiments on dogs, and in some observations made on patients having accidental biliary fistulæ, it was found that purgative doses of calomel notably lessen the secretion of bile. To explain the presence of bile in the stools notwithstanding diminished secretion, it was then assumed that calomel greatly increases the peristaltic contractions of the small intestine, especially of the duodenum, and thus hurries the bile already secreted downward so rapidly that reabsorption cannot take place. The presence of leucine and tyrosine in calomel stools rendered this view very plausible. But the fact that some purgatives, which act more rapidly than calomel, and doubtless strongly accelerate the peristaltic contractions of all parts of the intestines, do not produce markedly bilious discharges seemed to show that this assumption was incorrect.

The recent experiments of Wassilieff show conclusively that calomel produces bilious stools, by arresting decomposition in the intestines. He divided fresh ox-gall into three portions, each weighing two hundred grammes; to one portion were added three grammes of calomel, to another two grammes, and to the third none. They were kept in a warm room, and occasionally agitated. The portions containing calomel at once became green, and retained this color as long as the experiment was continued, which was six days. They readily responded to Gmelin's test for bile-pigment, and showed no trace of decomposition. The portion not containing calomel had become brownish-yellow in one day, did not exhibit the reaction of bile-pigment, and was soon putrid. Doubtless calomel exerts the same antiseptic influence in the intestines. Under ordinary circumstances the bile-pigments, bilirubin and biliverdin, become converted into hydrobilirubin, and hence cannot be detected in the fæces. Calomel prevents this decomposition, and by increasing peristalsis causes the unchanged bile-pigments to be evacuated. In the same manner it prevents further changes of leucine and tyrosine, and the formation of scatol and indol.

Calomel is a very effectual purgative in the morbid state called biliousness—marked by a sallow complexion, yellowness of the white of the eyes, a bitter taste, defective appetite, and sometimes nausea; headache, mental dulness, and depression; and sometimes by light-colored stools and sedimentary urine. By arresting decomposition and removing bile and other substances before they can be absorbed, it thoroughly relieves both the intestines and liver.

In small doses calomel has been found useful in the gastro-enteritis of children. Its utility is probably due chiefly to its antiseptic action.

Administered in doses of from five to seven grains, for one or two days, in the first week of typhoid fever, calomel somewhat lowers the febrile temperature and renders the disease milder. As other purgatives are less useful, it probably exerts a destructive influence upon the micro-organisms which cause the disease.

As a rule, calomel is indicated as a purgative in all acute affections of the intestines resulting from fermentation and putrefaction.

Together with jalap or rhubarb, it is sometimes administered in the early stage of inflammatory disorders of the internal organs. Though not useless, it produces very much less effect on the quantity of fluid in the blood-vessels and on the blood-pressure than large doses of the saline purgatives.

Calomel should not be used in habitual constipation.

It is usually ordered in powder with sugar, or with jalap, rhubarb, or bicarbonate of sodium. ℞. Hydrarg. chlor. mitis, gr. v.; sacch. albi, gr. x. M. Sig.: Take at once. ℞. Hydrarg. chlor. mitis, gr. iij.; pulv. jalapæ, gr. x. M. Sig.: Take at once in syrup or molasses. ℞. Hydrarg. chlor. mitis, gr. v.; sodii bicarbon., gr. xv. M. Sig.: Take in molasses or syrup. In all cases, if calomel have failed to act after eight or ten hours, a saline purgative or castor-oil should be given.

Massa Hydrargyri.—Blue mass is a somewhat uncertain purgative when given in doses of from five to ten grains. It is, therefore, usually combined with rhubarb, aloes, podophyllum, or compound extract of colocynth, or, if given alone, a dose of castor-oil, Rochelle salt, Epsom salt, a senna draught, or a seidlitz powder, is administered after eight or ten hours. It is held to be efficient in biliousness, and is usually given in the evening.

Hydrargyrum.—Metallic mercury in large doses quickly passes through the alimentary canal in consequence of its great weight. Probably the dragging and stretching of the mucous membrane, resulting from the presence of large quantities, excite very powerful peristaltic contractions, which rapidly carry the metal through the intestines.

Metallic mercury has been employed in intestinal obstruction when all other ordinary means had failed to give relief. Bettelheim (*Deutsches Archiv f. kl. Med.*, Bd. 32, p. 53) carefully studied seventy cases of obstruction, reported during the last fifty years, in which mercury was used. In fifty-seven cases a cure resulted, that is, the obstruction was relieved either temporarily or permanently. In no case did it cause rupture, inflammation, or gangrene of the bowel, while in some instances it saved life. Bettelheim therefore considers it proper to administer mercury in cases of obstruction due to fæces, ascarides, and even to intussusception or torsion, if other ordinary means have failed to give relief.

The dose of metallic mercury varies from one to ten ounces.

Drastic Purgatives.—Of the cathartics which operate violently and produce serious irritation of the intestines, when given in excessive doses, only the following are commonly employed: Jalap, scammony, colocynth, podophyllum, gamboge, croton-oil, and elaterin.

Jalapa.—Jalap is the mildest drastic, and resembles senna in its action. In doses of fifteen to thirty grains it usually soon causes a feeling of discomfort in the epigastrium, and sometimes nausea. After two or three hours tormina and several liquid stools occur. Smaller doses, five to ten grains, act gently, producing one or two pultaceous evacuations. In very excessive doses jalap causes vomiting and profuse rice-water discharges, with great depression.

The resin of jalap, in doses of one to three grains, acts as a laxative, but in larger doses, from five to fifteen grains, produces watery stools in a few hours.

According to recent investigations, jalap does not act well when bile is absent from the intestines. In experiments on dogs it was found to increase moderately the secretion of bile.

On account of its rapid, safe, efficient, and hydragogue action, jalap is frequently employed when a brisk cathartic is indicated. In cases of acute constipation, and in inflammatory diseases, it is usually associated with calomel, and in ascites and anasarca with bitartrate of potassium. The officinal *pulvis jalapæ compositus*, consisting of 35 parts of jalap and 65 parts of cream of tartar, is generally preferred to other hydragogues in dropsy. In doses of half a drachm to one drachm, it usually produces watery discharges in a few hours.

The resin of jalap may be given in doses of from one to eight grains in powder or emulsion. ℞. Resin. jalapæ, pulv. acaciæ, āā gr. viij.; sacch. albi, ʒ ss. M. Div. in part. æqual. iv. Sig.: One powder every two hours till the bowels move. ℞. Resin. jalapæ, gr. viij.; pulv. acaciæ, sacch. albi, āā ʒ j.; aq. menth. pip., ℥ ij. M. Sig.: One tablespoonful every two hours. Sometimes resin of jalap is given in combination with calomel. ℞. Resin. jalapæ, hydrarg. chlor. mitis, āā gr. iv.; sacch. albi, ℈ j. M. Div. in part. æqual. iv. Sig.: One powder every two hours.

Jalap is contra-indicated in inflammatory affections of the alimentary canal.

Scammonium.—Scammony resembles jalap in action, but is less certain, sometimes producing little or no effect, at other times acting harshly, with griping and tenesmus. Usually it is followed by watery stools in a few hours. The presence of bile in the intestines is necessary for its action. It is rarely used except in combination with other purgatives, as in the officinal *compound cathartic pills.* The dose of scammony, to act briskly, is from ten to twenty grains, and of its resin, from five to ten grains.

Colocynthis.—Large doses of colocynth produce numerous fluid evacuations, with griping and tenesmus. Excessive doses cause sanguinolent stools, great abdominal pain, intense depression, and sometimes death.

Small doses, one to three grains, act gently, producing loose stools without notable griping. But if frequently repeated, such doses soon cause tormina and tenesmus, and slimy stools.

According to Brieger, small quantities of extract of colocynth, 0.02 gramme dissolved in 2.0 grammes of water, injected into isolated portions of intestine, produce slight hyperæmia and peristaltic contraction, but no accumulation of fluid. But larger quantities produce decided inflammation and an effusion of bloody fluid.

In experiments on dogs Rutherford found colocynth to cause an increased flow of watery bile.

On account of its harsh operation, colocynth is rarely employed alone to produce brisk purgation; but in small doses, in combination with other laxatives, it is frequently given in habitual constipation.

The dose of the extract of colocynth, as a laxative, is one-sixth to two-thirds of a grain, and of the compound extract, from one to five grains. The latter preparation is sometimes given in doses of five to fifteen grains, to purge briskly. Usually the extract of hyoscyamus, or the extract of belladonna, is combined with it, to prevent griping. ℞. Extr. colocynth., gr. j.; aloes, gr. vj.; extr. hyoscyami, gr. vj. M. Ft. pil. vj. Sig.: One pill at bedtime. ℞. Extract. colocynth. comp., gr. xij.; extr. bellad., gr. ij. M. Ft. pil. vj. Sig.: One pill at bedtime.

Cambogia.—Gamboge is held to be still more irritant than colocynth. In experiments Rutherford found, after large doses, violent irritation of the duodenum and small intestine generally, with profuse catharsis, but no increase of the bile-flow.

It is, perhaps, never given alone, but is sometimes added to other purgatives to increase their action, as in the compound cathartic pills. Very small doses, one-sixth to one-half grain, are said to produce pultaceous stools without much griping. Generally doses of three to four grains cause some nausea and colicky pain, and several watery stools. Excessively large doses, one drachm, have caused fatal gastro-enteritis.

Formerly gamboge was frequently employed in obstinate constipation, ascites, anasarca, paralysis, insanity,

gout, and skin diseases. Generally it was given together with aloes, jalap, bitartrate of potassium, and calomel. ℞. Cambogiæ, gr. iv.; pulv. jalapæ comp., ʒ ij. M. Div. in pulv. iv. Sig.: One powder every two hours till the bowels act, in cases of dropsy.

Pilulæ Catharticæ Compositæ.—The compound cathartic pills contain small quantities of aloes, scammony, colocynth, jalap, gamboge, and calomel. On account of their complex composition they are supposed to affect all parts of the intestines, and to increase the secretion of bile. One pill usually acts as a laxative, while three or four produce free purgation. They are suitable to acute constipation not complicated with inflammation of the intestines, but should not be employed in habitual constipation.

Podophyllum.—This purgative, even in large doses, usually acts slowly, from six to ten hours elapsing before the bowels move. Doses of ten grains rarely cause marked incidental effects, but twenty or thirty grains are usually followed by nausea, and sometimes vomiting and depression, and severe colicky pain. The evacuations sometimes have a dark color, from which it was assumed that they contain a large quantity of bile. In experiments on dogs Rutherford found that moderate doses of podophyllin cause an increased flow of bile.

The resin of podophyllum, commonly called podophyllin, is used as a laxative. Doses of one-eighth to one-half grain usually produce a gentle movement in eight or ten hours. Large doses, from two to four grains, cause nausea, sometimes vomiting, severe griping, and numerous stools, which may be slimy and bloody and followed by intense depression.

Podophyllin is not suitable in cases requiring brisk purgation. But in chronic constipation it is much used, because it continues to act for a long time without necessitating an increase of dose. It is frequently employed when symptoms are present which show that the secretion of bile is abnormal. Usually it is given in pillular form, with extract of hyoscyamus or extract of belladonna. ℞. Podophyllini, gr. ij.; extr. hyoscyami, gr. viij. M. Ft. pil. No. viij. Sig.: One pill at bedtime. It has also been given in solution as follows: ℞. Podophyllini, gr. ij.; alcohol. dil., ℥ ij.; tinct. zingiberis, ʒ ij. M. Sig.: A teaspoonful in a wineglassful of water.

Podophyllotoxin is said to act more regularly than the officinal resin. It has been given to adults in doses of one-sixth to one-fourth of a grain, and to children in doses of one-sixtieth to one-twelfth of a grain. Brun employed it in alcoholic solution as follows: ℞. Podophyllotoxini, Gm. 0.05; spir. vini rectif., Gm. 7.5. M. Sig.: From five to fifteen drops in sweetened water.

Oleum Tiglii.—Croton-oil is a very energetic drastic, a drop sometimes producing from five to fifteen watery evacuations. Often the first evacuation occurs in one or two hours.

The susceptibility of different persons to its action varies, in some one drop acting intensely, in others producing only a few semiliquid stools. In rare instances purgation does not result from the dose mentioned, but there takes place general disorder, marked by palpitation of the heart, pain in the extremities, severe headache, giddiness, and prostration.

Frequently the action of croton-oil is attended by symptoms indicating irritation of the stomach and intestines—a sensation of heat in the epigastrium, more or less nausea, sometimes vomiting, borborygmi, colicky pain, and tenesmus.

Excessive doses quickly induce vomiting and purging, and great prostration. Twenty drops have proved fatal.

Croton-oil is used when a powerful purgative is indicated, and milder medicines have failed to act or cannot be administered. Sometimes this is the case in obstinate constipation, lead-colic, and diseases of the brain and spinal cord. When brisk purgation is necessary, and swallowing is very difficult, the oil is preferred to more bulky cathartics, a drop being mixed with a little sugar, or a little bread-crumb, and placed on the back of the tongue.

The oil has been strongly recommended for the removal of tape-worm—one drop mixed with one drachm of chloroform and one ounce of glycerine, to be given early in the morning.

Croton-oil is usually given in pillular form. ℞. Ol. tiglii, gtt. j.; micæ panis, q. s. M. Ft. pil. iv. Sig.: One pill every hour. It is said that the oil acts more gently when combined with compound extract of colocynth and extract of belladonna. ℞. Ol. tiglii, gtt. j.; extract. colocynth. comp., gr. viij.; extr. bellad., gr. j. M. Ft. pil. iv. Sig.: One pill every two hours. Sometimes it is given mixed with sugar. ℞. Ol. tiglii, gtt. j.; sacch. lactis, ʒ j. M. Div. in part. æq. iv. Sig.: One powder every hour. It may also be mixed with castor-oil, or made into an emulsion, as follows: ℞. Ol. tiglii, gtt. j.; pulv. acaciæ, ʒ ij.; syr. amygdalæ, ℥ ss.; aq. destill., ℥ iijss. M. Ft. emuls. Sig.: One tablespoonful every hour.

Elaterinum.—Elaterin is the most powerful and drastic of all purgative medicines. The twentieth of a grain, given to an adult, will generally produce watery stools in one or two hours. Sometimes this speedy action is not attended by marked incidental effects; but often, especially if it is given alone, nausea, severe griping, borborygmi, and some prostration are produced. Excessive doses may cause intense gastro-enteritis and fatal collapse.

Elaterin is employed in ascites and anasarca, when gentler hydragogues have failed to act efficiently. As a rule, it is given only every other day, and not continued longer than a week or ten days, lest it excite serious intestinal inflammation. After an interval of a week its use, if necessary, may be resumed. It is contra-indicated in dropsies complicated with intestinal irritation, and must be used with extreme caution in very young, aged, and feeble patients.

It may be ordered in solution, pill, or powder. ℞. Elaterini, gr. ½; alcohol., ℥ ss.; acidi nitrici, gtt. ij. M. Sig.: From twenty to forty drops in an aromatic water. ℞. Elaterini, gr. ¼; extr. hyoscyami, gr. vj. M Ft. pil. vj. Sig.: One pill every hour till stools take place. ℞. Elaterini, gr. ¼; sacch. albi, ʒ j.; ol. menth. pip., gtt. ij. M. Div. in part. æqual. vj. Sig.: One powder every hour until the bowels act.

General Indications.—Purgatives are used (1) to evacuate the intestines; (2) to diminish hyperæmia of remote parts or organs; (3) to promote the absorption of exudations and transudations; and (4) to eliminate noxious substances.

1. *All purgatives evacuate the contents* of the intestines; but when this is the sole indication for their use, only laxatives and mild purgatives should be given. In chronic or habitual constipation those laxatives are most suitable which act slowly, producing normal or nearly normal fæcal evacuations, without losing their activity in small doses after frequent repetition, and without interfering with general nutrition. Experience has shown that aloes possesses these properties in the most eminent degree. Podophyllin, rhubarb, and compound extract of colocynth are also eligible. The saline laxatives are sometimes used in habitual constipation; but as their prolonged use is followed by impairment of nutrition, they should not be given to feeble patients unless required by other indications.

In occasional or acute constipation any laxative or mild purgative may be employed. If hardened fæcal masses are present in the intestines, the saline laxatives and castor-oil are most suitable. Sometimes all the mild purgatives fail to act in acute constipation, especially when the cause of the constipation is still present, as in lead-poisoning. Drastics are then appropriate, carefully used, and croton-oil is usually preferred. Metallic mercury has been successfully used after all ordinary purgatives had proved ineffectual.

To remove poisons and irritating substances from the intestines, those purgatives which act speedily and gently should be preferred, especially castor-oil and salines. When irritation of the intestines results from decomposition or fermentation, calomel is the best purgative.

2. *To diminish hyperæmia* of remote parts or organs, purgatives which act rapidly and produce semiliquid or

watery discharges are required. Mild purgatives deplete indirectly by hastening the intestinal secretions and partially digested food downward so rapidly that absorption is impeded. Saline purgatives, in strong solution, excite a copious secretion of watery fluid, and thus directly deplete the blood. Drastics act in a threefold manner, accelerating peristalsis, increasing secretion, and exciting intestinal hyperæmia. The choice of a purgative will, therefore, depend upon the intensity and duration of the disease to be influenced, the organ affected, and the character of the general symptoms. In congestion of the liver, calomel, followed by a saline laxative, is the most suitable purgative. In congestion or inflammation of most organs, saline cathartics and compound infusion of senna are usually employed; but in very severe congestion or inflammation of very important organs—such as the brain and spinal cord—drastics are preferred, especially croton-oil.

3. *To promote absorption of exudations* and transudations, the hydragogues are most suitable. Generally the saline hydragogues, given so as to produce copious watery stools, soon cause rapid absorption. In cardiac dropsy they often diminish the dropsical swelling very notably in a few hours. Of the drastic hydragogues the compound powder of jalap and elaterin are the most useful. Generally the former is preferred on account of its mild action. But when it fails to act efficiently, or when an effusion of serum occurs rapidly, and in such large quantity as to produce extreme distress, such as alarming dyspnœa in pleuritis, elaterin is usually given. Sometimes it so rapidly induces absorption of the effusion as to give decided relief in a few hours.

4. *To eliminate noxious substances*, calomel, salines, and drastics are used. The utility of calomel in biliousness and congestion of the liver is in part due to the rapid removal of irritating and decomposing substances from the alimentary canal. Saline laxatives, especially sulphate of magnesium, are indicated in chronic lead-poisoning, to remove the poison from the intestines as fast as it is eliminated by the liver. They are also suitable in cases of uræmia, especially if at the same time it is necessary to induce absorption. In uræmic coma, croton-oil is sometimes preferred to milder purgatives.

CONTRA-INDICATIONS.—All purgatives are contra-indicated in peritonitis, intestinal hæmorrhage, perforation of the bowels, strangulated hernia, and extreme debility.

Brisk purgatives are generally inappropriate during pregnancy, especially if previous abortions have occurred, and during menstruation. They should not be used if there exist severe rectal lesions, or a tendency to looseness of the bowels. Even laxatives are contra-indicated in habitual constipation, until all other known means have failed to establish a normal habit of defecation.

Samuel Nickles.

PURPURA. A disease of the skin characterized by the development of variously sized and shaped, smooth, reddish or purplish hæmorrhagic patches, which may or may not be elevated above the surface, and which do not disappear under pressure.

The affection may conveniently be considered under two heads, *idiopathic* and *symptomatic* purpura.

IDIOPATHIC PURPURA is usually considered to include two varieties, P. simplex and P. hæmorrhagica, although these divisions (like those of idiopathic and symptomatic) are arbitrary, and the two varieties may run into each other with intermediate cases.

Purpura simplex is characterized by the appearance, in successive crops, of numerous petechial spots in the skin and visible mucous surfaces. These are usually attended with little or no constitutional disturbance. Occasionally, however, malaise, loss of appetite, and fatigue on exertion are experienced for some days before the cutaneous lesions appear. These generally make their appearance suddenly, often in the course of a night, at other times more gradually.

The lesions are usually bright red in color at first, becoming more purplish in hue later. They are sharply defined, roundish, ovalish, or irregular, sometimes circinate in form, and vary from the size of a pin-point to that of a pea or small coin. They usually occur in numbers and symmetrically, the lower limbs being a favorite seat, and in particular the flexor surface of the thigh. They may occur sparsely scattered over the whole body. Usually there are no subjective symptoms connected with the appearance of purpura simplex; occasionally there is a little itching on the first appearance of the spots, and they are not infrequently tender on pressure.

Purpura simplex is more frequently observed in the old than in the young. It may last from a fortnight to several months, or even longer, the lesions coming out in successive crops. The affection occurs in the well-nourished and apparently healthy, as well as in the debilitated.

The immediate cause of purpura simplex is not infrequently found in fatigue, exposure to damp and cold, moral shock, and occasionally malarial influences. The affection usually lasts a few weeks only, but may be prolonged for months, or even a year or more, by the appearance of successive crops of eruption.

Another form of idiopathic purpura is that known as *purpura urticans.* The eruption here shows itself first as a roundish papule, which gives place in a few hours to a purpuric macule, resembling in every respect the macule of P. simplex above described. Occasionally, however, a congestive or bright-red circle is seen surrounding the purpuric spot. The burning, itching, and tingling of ordinary urticaria are rarely present. On the other hand, there may be pains in the limbs, and, occasionally, articular swellings; and localized œdema, sometimes soft, at other times red and painful, is occasionally noticed about the joints or in the length of the limbs. The common seat of the lesions is upon the lower limbs. The eruption may be preceded or accompanied by slight general malaise, and occasionally some feverishness. It resembles closely in all other symptoms, course, etc., purpura simplex, excepting that it is frequently accompanied by sick headache (migraine), dyspepsia, congestion about the head, difficulties of sight and hearing, hæmorrhoids, and rheumatic pains.

Purpura rheumatica, or peliosis rheumatica (πελος, livid), is usually found occurring upon the lower limbs, about the tibio-tarsal articulations or the knees, and on the lower and inner aspect of the thighs. The eruption consists of petechiæ, more rarely of true ecchymoses, and is commonly symmetrical, although it is sometimes seen limited to a knee or an elbow. Urticaria-like papules are not infrequently observed co-existent with the petechiæ.

P. rheumatica may occur suddenly and without prodromes. Ordinarily, however, pricking, weight, and tension in the part to be affected precedes the appearance of the rash, which is accompanied by some rise of temperature, rarely above 101.3° F.

The articular pains are usually experienced in the insteps, the knees, and the carpal region. The effusion is slight, movement of the affected joints is painful, and pressure near the ligaments gives rise at times to sharp pain.

Œdema of the cellular tissue is often a marked feature of the disease. The skin becomes stretched, reddish, pits, and is painful on pressure. Sometimes the œdema is extreme and seems almost phlegmonous in character, with extensive ecchymoses. Soyer has given to this variety the name of *febrile purpuric œdema.*

Very exceptionally the rheumatic symptoms may become generalized, and even heart complications may follow, but usually we have purpura complicated with slight rheumatism. An acute, febrile, general rheumatism with purpura as an accompaniment is very uncommon.

Though purpura rheumatica is usually a comparatively slight malady, yet cases have been recorded in which hæmorrhage from the stomach and bowels, gangrene of the face, limbs, intestine, etc., have gravely complicated the attack.

The duration of the attack of purpura rheumatica is brief, but the disease may be, and usually is, prolonged by successive attacks for weeks, and even months. It usually terminates in recovery, and relapses are rare.

The affection is most apt to attack persons in whom a

rheumatic taint exists. Nervous exhaustion, privation, and exposure to cold are among the exciting causes.

Couty and Henoch have described a variety of purpura to which they attribute a nervous origin. This form of purpura is characterized by three symptoms: 1, a purpuric eruption; 2, gastro-intestinal disorder; 3, cutaneous œdema.

The eruption is petechial and makes its appearance suddenly, often assuming the urticarial form and involving by preference the limbs, particularly the lower limbs, the abdomen, the genitalia, and, exceptionally, the trunk and face. The extent of the lesions varies from one or two small spots to even sheets of eruption. The duration of the lesion is from four to six days. Successive attacks vary greatly in frequency and severity.

The gastro-intestinal disturbances are chiefly bilious vomiting, and successive attacks of colic, accompanied by retraction or inflation of the abdomen, and not followed by stools. These attacks of colic usually last only an hour or so, but may continue one or two days.

The œdema characteristic of this form of purpura may be peri- or intra-articular, and may occupy a greater or less portion of the limb. Sometimes the affected part is pale and painless, at other times it is red and painful. Occasionally gangrene supervenes. The various symptoms may occur in regular order in successive attacks, or they may be intermingled.

Under the name of *myelopathic purpura* Faisans has described a similar form of the disease, the cause of which he has traced back, in a number of cases, to some nerve disturbance, as chronic affections of the cord, transverse myelitis, secondary spinal cancer, and tuberculosis. Faisans lays stress upon the frequently urticarial form of the eruption, on its symmetrical occurrence, and on the possibility of the distribution of the spots along the course of the sensory nerves, similar to that of herpes zoster.

The arthralgia, in Faisans' opinion, is a marked symptom, and is peculiar with respect to its multiplicity and extreme mobility. The ankle, knee, wrist, and elbow are most frequently attacked, but all the joints may be involved in turn. The eruption in Faisans' cases usually was in close connection with the joint-trouble, being most marked in the neighborhood of the affected articulation. Hyperæsthesia and anæsthesia were observed in connection with the purpura. There was rarely fever. While Conty regards the gastro-intestinal attacks as analogous to those of lead colic, Faisans looks upon them as resembling the pains of locomotor ataxia. The latter also regards this form of purpura as rather of a medullary than of a sympathetic nervous origin. Faisans says that the attacks may follow acute hyperæmia of the posterior fasciculi of the cord, resulting in intense congestion of the skin, with trophic disturbance of the smaller vessels facilitating their rupture.

In this connection reference may be made to the interesting observations of Straus on tabetic ecchymoses. These ecchymoses appear in a certain number of ataxic patients, following severe attacks of fulgurating pains, and occur, like other forms of purpura, chiefly upon the limbs. The ecchymoses resemble contusions most closely, but are not painful upon pressure. They are irregularly circular in form, and vary from the size of a pea to that of a silver dollar. The number also varies from one to several upon each limb. Their extent seems to be dependent upon the severity of the previous attack of pain.

The seat of these tabetic purpuras is of interest. They are, as a rule, situated on the member or part which has been the chief seat of pain, usually not directly over the affected point, but on the proximal side. Occasionally the other side of the body, corresponding to that attacked by the pain, is the seat of the eruption. According to Straus, the lesions do not seem to be arranged along the lines of distribution of the nerves. Charcot, however, takes a different view.

As regards the frequency of tabetic purpura, Straus has observed it twice in twelve cases of locomotor ataxia.

Under the name of *purpura hæmorrhagica* has been described a group of cases having the one point in common, that the eruption on the skin has also been accompanied by hæmorrhages from the cavities of the body, but otherwise widely differing from each other in the symptoms presented. Recent writers are inclined to separate these cases, and assign the greater part to scorbutus, and the rest to the other divisions of purpura which have been, or are to be, here described.

The name of Werlhof, a German physician of the last century, having been given to this affection (morbus maculosus Werlhofii is the entire clumsy title), Lasègue took the trouble to look up Werlhof's original paper on the subject, in order to find out what that author had described. The affection described by Werlhof is characterized by the absence of fever, prodromal symptoms, or concomitant symptoms worthy of mention. The affection begins by a more or less considerable hæmorrhage, rarely profuse, usually from the gums, only occasionally from the nose. There is at this time no hæmatemesis or other visceral hæmorrhage. In the course of from twenty-four to forty-eight hours after the first symptoms, the eruption, more or less confluent, has spread over the lower limbs first, and then in some cases over the arms and trunk. The face is never attacked. The spots are punctate, indolent, and do not blanch under the pressure of the finger.

By the third day larger hæmorrhagic patches and suggillations occur upon the lower limbs, in some cases accompanied by ecchymoses on the mucous surface of the mouth. The hæmorrhages or hæmorrhagic exudations continue in variable quantity; if they are severe, blood may be vomited or passed at stools. Weakness with slight fever, diminution of appetite, and possibly lassitude without actual pain in the limbs, are observed. When the affection has thus reached its height, rapid improvement takes place, and by the end of from eight to fifteen days the patient is well, without having to pass through a stage of convalescence and without suffering from any sequelæ.

From this summary of Werlhof's views it can be seen that writers like Du Castel and Mollière are justified in attempting to do away with the terms "morbus maculosus Werlhofii" and "purpura hæmorrhagica." As Du Castel says, "It is not a species, it is a group—I should say a medley—where the most dissimilar forms of disease *swear to find themselves in juxtaposition.*"

Purpura scorbutica shows itself first by marked constitutional symptoms. Increasing cachexia, extreme lassitude, heavy, dull pains throughout the body, with fatigue upon the least movement, are among the prodromal symptoms. The skin is dry, of a livid yellowish, earthy color. The mucous surfaces are pale, and there is frequently slight bloating of the face. In severe cases violent pains in the trunk and limbs, most intense about the knees and thorax, are experienced. The thoracic pain sometimes even interferes with respiration, the thorax feels as if encircled by a band of steel.

The first symptoms of purpura, which are apt to show themselves after eight days of prodromes, consist in the appearance of a sort of purpuric goose-flesh, hæmorrhage taking place about the hair-follicles of the lower limbs. According to Lasègue and Legroux, in their admirable report upon scurvy in Paris during the Franco-German war, the follicular petechiæ appear under the form of small roundish elevations of a deep violaceous-red color in robust patients, and of a bluish-lilac color in individuals much enfeebled by previous disease. The lesion is traversed by a hair, or rather a grayish point can be seen in its centre, made up of a little heap of dried epidermic scales under which a hair curls upon itself. On lifting this little epidermic mass with the point of a needle the imprisoned hair is released, and is then seen to be vitiated in its growth, thinned, twisted, and occasionally split at its extremity, or atrophied and deviating from its normal direction.

This goose-fleshlike purpuric eruption is caused by a sub-epidermic hæmorrhage about the hair-bulbs, and does not extend more than one or two millimetres beyond the hair which is its centre.

This form of purpura occurs by preference upon the external and anterior aspect of the leg, and next in frequency upon the same aspect of the thigh. It is also found upon the extensor surface of the forearm, rarely upon the trunk. Some single hairs of the eyebrows have been observed to be surrounded by the eruption. In the case of hairy men the eruption may at times be confluent. In women it is usually discrete. In the dirty and careless it is more marked.

The lesions appear suddenly and simultaneously; they may last from one to two months and then disappear, leaving no trace, excepting that some hairs are apt to be distorted from pressure upon their roots.

In mild cases of purpura scorbutica the petechial eruption may be the only pathognomonic sign. In many cases of scorbutic purpura, in fact in most of them, the mucous membrane also shows certain symptoms. At first, the congested gums show a blue venous band running along their free edge, of a millimetre or so in width, while the swollen interdental processes look almost like currants. In severe forms of the disease the ecchymosed gums may be greatly tumefied, even rising up so as to conceal the teeth and prevent mastication, being covered with fungous growths and bleeding on the lightest touch. The teeth are loosened and fall out, the breath is fetid, and in strumous persons the sub-maxillary lymphatic glands may become inflamed. The maxillary bones may even become necrosed. Hæmorrhagic effusions frequently take place into the mucous membrane of the mouth, particularly about the hard palate and velum, in the form either of petechiæ or of large ecchymoses. Lasègue and Legroux call attention to the important fact that the gingival changes are often wanting in scurvy, and are far from giving a highly characteristic symptom. Though this may be the case on land and in certain epidemics, yet among sailors the gums are often severely affected. Possibly the previous condition of the teeth may influence this symptom.

At a later period in the course of purpura scorbutica more or less extensive and deep-seated ecchymoses, resembling precisely the effect of ordinary contusions, are commonly observed. These are usually found upon the lower limbs and on dependent portions of the body, as the instep, calf, and popliteal region. However, in persons who use the arms in working, these limbs, or the one of these most used, may be the chief seat of the lesions. Old scars are also frequently attacked.

These ecchymoses correspond to hæmorrhagic exudations into the subcutaneous cellular tissue or the deep muscular masses. Sometimes they are large and ill-defined, more rarely they may be observed as sharply circumscribed tumors.

The larger ecchymoses may not, at first, give any sign of their presence by outward discoloration, but movements become painful and walking may be impossible. In the neighborhood of the effusion the skin is drawn, smooth, and hot to the touch. Pressure gives rise to severe pain. The muscular masses are peculiarly rigid, the limb sometimes looking as if distended by an injection of wax, which had penetrated into all the interstices. Œdema, hard and localized, may show itself, with diffuse limits; but occasionally these are sharply defined, like the groove produced by the garter in a swollen limb. The points most frequently affected are the muscular masses of the calves, the fatty areolar tissue about the tendo Achillis, the flexor tendons of the thigh, the popliteal space, and the posterior muscles of the thigh.

These infiltrations make their appearance suddenly, in the course of a few hours, and may be accompanied by slight feverishness. Walking is almost impossible, the limbs seem benumbed. Spontaneous internal pain may be experienced if the hæmorrhagic effusion occurs between a bony surface and the inextensible skin. Œdema also occurs at this stage of the disease, due to embarrassment of the circulation, and is to be distinguished from the cachectic œdema, the latter being increased whenever the patient puts foot to the ground.

When resolution, always a slow process, sets in, the skin becomes brown, soft, tense, and shining, the epidermis looks as it does when an attack of eczema is passing off, while the derma is hard, compact, woodeny, and almost incompressible. Movement gives rise to pain, the limbs are kept immovable, and the joints bathed in the infiltration become rigid. Sometimes there is a slight intra-articular effusion. As the effusion is absorbed the woodeny condition becomes more marked. When the patient first begins to walk, a fresh eruption of petechiæ shows the embarrassment of the venous circulation. The color of the skin, after passing through various shades of blue, black, green, and yellow, takes on a bronze tint, which sometimes lasts a long time.

In connection with the purpuric eruption it may be noted that abrasions, scratches, etc., are apt to result in unhealthy ulcers.

The urine in purpura scorbutica is scanty and high-colored, and yields a smaller amount of urea than normal. The albuminoids are increased, and extractive matters are also more abundant than normal, showing excessive molecular disintegration.

In severe cases of purpura hæmorrhagica, hæmorrhage from the stomach and intestine, the bladder, the nose, the hæmorrhoidal veins, etc., may occur. Gingival, nasal, intestinal, and uterine hæmorrhages are most common. In the extreme forms of the disease the cachectic œdema spreads and becomes generalized—a very unfavorable symptom. Diarrhœa succeeds constipation, serous or sero-sanguinolent effusion occurs in the larger articulations, in the visceral serous sacs, and under the detached periosteum. Scorbutic periostitis, necrosis of the maxillæ or tibiæ, separation of the epiphyses, dislocation of the callus of old fractures, and sometimes mortal syncope, may supervene. Death results from a general breaking down at all points, the intellectual functions alone remaining intact until the last.

Purpura scorbutica usually runs a rapid course. In favorable cases it may last only a week or a fortnight. Severe symptoms are not apt to supervene unless the affection has lasted for several months. Death may occur in syncope, in an attack of dyspnœa, or as a result of exhaustion from hæmorrhage. Convalescence is always prolonged, and is accompanied by extreme weakness. Fever is usually absent, but may show itself in a slight degree after considerable hæmorrhages.

Lasègue and Legroux consider two forms of scorbutus to exist: a sthenic, observed in robust persons, in which extensive hæmorrhages may occur, and an asthenic, occurring in enfeebled individuals, where there is less liability to hæmorrhage but more tendency to cachexia.

Symptomatic Purpura.—For the sake of convenience this division of purpura is made to include these cases in which the eruption is clearly a secondary symptom, occurring in the course of some well-marked disease, though it would be a difficult matter at times to draw the line between primary or idiopathic and secondary or symptomatic purpuras.

Secondary purpura occurs in the course of advanced cachexiæ or of infectious diseases, or from toxic influences. It may be simple or hæmorrhagic in character.

Cachectic purpura is observed in the course of diseases of slow evolution, as cancer, tuberculosis, diseases of the spleen, kidneys, ganglia, etc. It is not until the patient has arrived at an advanced stage of cachexia that the eruption appears. It runs its course without general malaise, without fever, and without pain. Its usual seat is upon the lower limbs, and sometimes upon the forearms, where it occurs in the form of small, slightly elevated spots, the centre of each usually being a hair-follicle. Ecchymoses of any considerable size are rare. The gums are not apparently affected. The purpuric eruption does not seem in any way to modify the course of the disease. In a few cases, particularly of acute tuberculosis, internal hæmorrhage complicates the affection, of course rendering the prognosis more grave.

Senile purpura is a form of cutaneous hæmorrhage which chiefly affects the upper extremities of elderly women whose arms are exposed to cold and to external injuries. It appears on the forearms in the form of spots

of varying size. Each spot lasts from seven to ten days, but the condition may persist for years.

Infectious purpura shows itself in the course of severe pyrexiæ or toxic conditions. It forms one of the series of symptoms in such affections as typhus, plague, yellow fever, and phosphorus-poisoning; or it may show itself on rare occasions in the severer forms of variola, scarlatina, measles, or cerebro-spinal meningitis. In the former class of cases the appearance of purpura does not materially increase the gravity of the prognosis, but in the latter forms of disease it is a symptom of great gravity, and is not infrequently the precursor of a series of severe visceral hæmorrhages (see Bulkley, Neumann, and other authors on purpura variolosa).

The cutaneous lesions are diffuse, and may occur on any or all parts of the body. They are a mixture of petechiæ and of extensive ecchymoses of a deep livid color, sub-conjunctival ecchymoses, hæmaturia, metrorrhagia, gastric and intestinal hæmorrhages, hæmoptysis, etc. The general condition is profoundly influenced; high fever with anxious respiration supervenes, and the patient rapidly succumbs with symptoms of ataxo-adynamia, or is carried off by excessive hæmorrhages. The purpuric eruption is often preceded by the appearance of diffuse exanthemata, as the scarlatiniform or rubelliform rash of variola.

Similar purpuric eruptions occur in connection with affections of the liver and spleen, such as icterus gravis and leucocythæmia.

To this class of purpuras belong those caused by the ingestion of various medicines, as iodide of potassium, salicylic acid, etc., though these purpuras are of a very much milder type, resembling purpura simplex, and not being accompanied by visceral hæmorrhages.

Mechanical purpura is observed as a result of tension in the blood-vessels, suddenly brought about by such causes as severe attacks of coughing in whooping-cough, or the convulsions of epilepsy. The purpura in this case consists in punctate hæmorrhages limited to the skin about the orbital cavity. It is rare to see generalized purpura in this variety; such an occurrence signifies an attack of extreme severity, or a marked predisposition to cutaneous hæmorrhages. Phlegmasia alba dolens, varicose veins, and certain forms of heart disease are apt to be accompanied at times by outbreaks of purpura. The significance of this form of the disease is trifling.

Mention may be made under this head of cutaneous hæmorrhages in hæmophilia (see art., Blood) following contusions or resulting from flea-bites. These last are apt to be mistaken for purpura, and a long article which appeared some years ago, from the pen of a Dublin physician, on a mysterious epidemic of purpura, was found to be based on a mistaken diagnosis in this respect.

It will be observed that purpura is produced under a very great variety of circumstances, and thus the very numerous clinical observations of the various forms of the affection have tended to overwhelm the student with a mass of facts which it is very difficult to arrange in any satisfactory system, or to approach from any common stand-point. The study of the pathology of the disease, however, throws light upon the subject, and must therefore be considered with some attention.

Changes in the Blood in Purpura.—These have been studied by a number of observers within the last few years, but the results as yet have not thrown much light upon the part played by them in the production of the purpuric extravasation. A greater or less diminution in the number of red corpuscles and in the amount of solid matters has been observed, and also inconstant variations in the amount of fibrin. In hæmorrhagic and infectious purpura the fibrin has been found to be diminished in quantity, while in purpura simplex and purpura scorbutica it has been found in increased quantity. In addition, the white corpuscles are frequently increased in number, the red corpuscles are altered in form, and bacteria and embryonal elements are present.

These facts are not of the first importance, nor do they explain the cause of the disease. It must, however, be remarked that an increase in the quantity of fibrin contained in the blood does not seem to prevent its escape from the vessels.

Lesions of the Blood-vessels in Purpura.—Fatty or amyloid degeneration of the capillaries has been accused of inducing hæmorrhages through fragility of the vascular walls, but positive observations on this subject are as yet too few in number to enable a positive statement to be made. The suggestions of atheroma of the capillaries, of thinning, softening, or porosity of the walls of the smaller vessels, of congenital or acquired fragility, are theories rather than the statement of observed facts.

B. W. Richardson describes three varieties of purpura, the aqueous, the saline, and the vascular, but these divisions are theoretical and are in some points contradicted by facts. For instance, chlorotic and hydræmic patients, whose blood is certainly watery to a typical degree, are not particularly liable to purpura.

Disturbances of Circulation in Purpura.—The study of the circulation itself in purpura should add to our knowledge of the pathology of the disease, but this has not until recently been carried out in a satisfactory manner. From recent investigations by French observers, it appears that congestion and stasis play an important part in the production of the purpuric lesion. Not only do the few microscopic examinations which have been made seem to prove this, but the fact that purpura is seen in connection with congestive rashes like those produced by medicines, the exanthemata, etc., seems to indicate the same thing.

We may consider it as probable, then, that disturbance of the capillary circulation, and augmentation of the blood-tension, are the points of departure of the purpuric spot, and that we may look for the origin of hæmorrhagic symptoms rather in blood-stasis than in an ill-understood condition of fluidity of the blood, or in a still less clearly understood vascular fragility.

As to the question how these disturbances of the capillary circulation originate, it appears that in many cases they seem to arise from some vaso-motor disturbance of innervation. The congestive patches, the œdematous eruptions, precursors of the hæmorrhagic spot in the numerously reported cases of exanthematic purpuras are indications of this perturbation.

The observations of Bouchard, who ligated the aorta after division of the cervical sympathetic, with the result of producing ecchymoses of the pinna of the ear on the corresponding side, support the view just stated. Other experimenters have succeeded in producing ecchymoses through lesions of the cord, so that experimental as well as clinical proof (Faisans, Straus, and others) can be adduced in support of this theory of the pathology of purpura.

Diagnosis of Purpura.—The diagnosis of purpura rarely offers any difficulty. The essential lesion, an extravasation of blood into the skin, is different from the lesions of all other skin affections. Pressure of the finger on the matured lesion fails to make it disappear, a condition which does not obtain in the papulo-macular syphiloderm or any other skin disease with which purpura is liable to be confounded.

Treatment.—In the treatment of purpura, attention must first be paid to the removal of the cause, if this can be ascertained. Nutritious diet, and, above all, if the hæmorrhage be extensive, rest in the horizontal position, are important. In purpura simplex, ergot, the preparations of iron, quinine, the mineral acids, together with frictions and cold baths, are beneficial. Purpura hæmorrhagica calls for prompt and decided treatment. Perfect rest in the horizontal position, with the same medical treatment as in purpura simplex, is appropriate. Oleum erigeron in five- to ten-drop doses on sugar, every two to four hours, has been highly recommended. Magee Finny says that ergot and belladonna are to be given first, and bark, ammonia, and the mineral acids later. In severe cases the ergot may be given hypodermically (one grain of ergotine repeated in four hours was thus administered by Minich successfully). Electricity has been used by Shand where other remedies have failed. In ordinary

cases, tincture of the chloride of iron, in doses of twenty to thirty drops thrice daily, alone or with digitalis and ergot, may be given. Turpentine and the acetate of lead, with opium, may also be given. Externally, sponging with vinegar, solutions of tannin, alum, etc., are often employed. Ice applied locally, and ice-water enemata when there is hæmorrhage from the bowels, may be employed with benefit.

Prognosis.—The prognosis of a case of purpura will depend much upon its nature and variety. That of purpura simplex or purpura rheumatica, exanthematica, or scorbutica, is in almost all cases eventually good, though the termination of the disease may long be delayed by successive relapses. On the other hand, infectious purpura almost always ends fatally. The prognosis of cachectic purpura varies with the cachexia, whether this is due to organic disease, to a curable affection, or to bad hygienic conditions. Those forms of purpura which occur in the course of other diseases, as the result of nervous or mechanical causes, are in most cases mere episodes in the history of the affections which they accompany. The febrile condition, when this exists, is an important element in the prognosis of purpura, rendering it more grave.

PUTREFACTION. Animal and vegetable tissues and juices undergo certain changes after death, if kept under proper conditions of moisture and temperature. These changes, termed putrefaction, decay, or rotting, amount to a mechanical softening in the case of solid substances, a discoloration if the material be colored, and, chemically, a splitting up of complex substances into simpler combinations, with the formation of ill-smelling products. Under the term fermentation changes of a similar character are also included, and the distinction between fermentation and putrefaction is not always an absolute one. The former designation is used particularly when the resulting products are of a useful nature, and besides, in the special case of transformation of sugar into alcohol under the influence of yeast.

Decay is not due to a chemical instability of dead organic substances, as was formerly supposed. It is the result of the growth of micro-organisms, especially bacteria, in and upon the material, and if these be excluded putrefaction does not occur. In order to explain how this statement can be proven experimentally, it is necessary to premise that bacteria exist throughout the world wherever putrescible material occurs; that these bacteria, on account of their ubiquity and minute size, are carried by the atmosphere in the form of dust, and that they are hence found deposited on the surfaces of all objects in inhabited localities. Wherever material which can serve as food for these micro-organisms is exposed, they will hence gain entrance into it inevitably. In order to prove that organic material can be kept without rotting, if protected against the entrance of bacteria, it must be taken from the interior of plants or animal bodies. If glass tubes be freed from adhering living bacteria by heat, and then be thrust into succulent fruits or vegetables through a part of the surface which has been purified by the momentary contact of a flame, the unaltered juices can be collected in such tubes and kept fresh for an infinite length of time (Van der Broeck, Roberts[1]). In a similar manner animal urine or blood can be gathered and kept unaltered permanently (Pasteur). The tissues of an animal recently killed may be cut out and transferred into closed flasks previously heated, where they will remain fresh forever (Meissner,[2] Hauser[3]). These experiments, however, require the utmost precautions. All the instruments used must be previously heated, and contact with the skin of the animal and all foreign objects must be absolutely avoided. Even in that case success is not invariable, because germs of putrefaction may be deposited from atmospheric dust. But with increasing skill of the investigator the percentage of successful experiments increases. Whenever putrefaction does occur in the case of any unsuccessful experiment of this kind, bacteria can be invariably seen with the aid of the microscope, while in those instances in which the material remains fresh no living micro-organisms can be found. The methods of examining, staining, and cultivating bacteria may be found described in the article, Micro-organisms.

Equally demonstrative experiments can be made in a simpler manner by placing organic substances, without such special precautions, into clean vessels and subsequently destroying all germs which may be present by vigorous boiling (Pasteur). As long as the vessels remain properly closed their contents will stay fresh and unaltered, but on allowing the atmospheric dust to enter them, or on inoculating them intentionally with a trace of putrid material, bacteria will at once begin to develop and putrefaction sets in. Pure air is not sufficient to start the putrefactive changes. The bottles may be plugged with cotton which allows the air to penetrate, but filters out the dust, or the air may be allowed to enter through narrow and tortuous tubes (Pasteur), in which the dust is deposited and caught, without producing any change in the contents. In order to perform such experiments successfully, however, it is necessary to know that all terrestrial objects are covered with germs of which a single one is sufficient for the development of infinite numbers; and that these germs can be destroyed with certainty only by a dry heat of at least 150° C. continued for at least three hours, or by steam of the temperature of 100° C., acting at least some three minutes (and in exceptional cases even a much longer time is required for sterilization). These experiments, varied in every possible manner, have invariably proved successful in the hands of those investigators who fully appreciated the difficulties surrounding them; while their exactness and absolute

* Particular acknowledgment is due to the author of this admirable résumé of our present knowledge of purpura, upon whose work the above article is based.

correctness were denied only by authors negligent in their precautions. Since the difficulty of excluding bacteria, or of destroying them after their entrance, has been fully recognized, all opposition to their importance has ceased. It can hence be stated as a well-proven dogma, that *putrefaction consists in a chemical decomposition of organic substances due to the life and activity of micro-organisms growing upon them.* A notable feature of these changes is the large amount of material decomposed by an apparently small mass of vegetable micro-organisms.

The microscope, however, shows that the disproportion between the material decomposed and the agency decomposing it, is not so great as it seems at first, since the minute size of the individual micro-organisms is fully compensated for by their enormous number.

A clear distinction must be made between the processes of putrefaction and fermentation on the one hand, and, on the other, chemical changes produced in certain organic substances by the action of non-organized soluble chemical ferments.

Instances of the latter kind are the dissolution (and peptonization) of albuminoids by pepsine and trypsine, the transformatisn of starch into dextrine and sugars by animal or vegetable diastase, the splitting of neutral fats into free acids and glycerine by ferments of the gastric and pancreatic juices, and numerous kindred examples occurring in animals and plants. In all such instances the active agent is a complex soluble organic, but not living, substance termed a ferment, which is produced by the living animal or vegetable cells, and can be extracted from them by suitable means. While these chemical ferments can decompose an amount of material very large compared with their own mass, there is still a limit to the possible proportion between chemical ferment and decomposed material, while of living micro-organisms a single one will ultimately multiply sufficiently to attack any amount of putrescible material. The essential difference consists, therefore, in the power of increase of living ferments, which dissolved chemical ferments do not possess. Practically it is sometimes difficult, except by microscopic investigation, to distinguish between the two classes of processes, since both are similarly influenced by about the same conditions of temperature, or by the addition of favorable or injurious chemicals. The formation of chemical ferments is not limited to the cells of higher animals and plants, but occurs as well in the bodies of the lowest living forms. In some instances they are secreted also by living micro-organisms, like yeast-cells and different forms of bacteria, and are of advantage to them in their preliminary solution and digestion of the material which they decompose. However, but few of such instances are as yet known, and the assertions of some chemists, that all putrefactive changes can ultimately be traced to soluble ferments secreted by the micro-organisms, are unfounded in their generality. In the light of our present knowledge, most of the instances of putrefactive and fermentative processes must be regarded as occurring in the interior of the bodies of living micro-organisms.

Conditions of Putrefaction.—The decomposition of putrescible material proceeds at the same rate as the growth and multiplication of the bacteria causing it, and is subject to all influences affecting the latter. Bacteria require a supply of nitrogen, carbon, and mineral salts as food, and unless the soil can furnish the necessary elements they cannot grow. The nutritive substances may, however, exist in a very great dilution dissolved in water. Thus even distilled water will allow some forms of bacteria to multiply in it. But there are vast differences between different forms of micro-organisms in their ability to subsist on soils of greater or less complex chemical nature. Thus some varieties can extract their supply of nitrogen out of ammonia-salts, while others cannot dispense with albuminoids for food. Albuminoids, especially in the form of peptone, are, however, the best soil for all bacteria.

Micro-organisms require for their growth a moist soil. Thoroughly dry material does not permit the development of bacteria and cannot be attacked by them. An acid reaction of the soil is unfavorable to most bacteria. Even those varieties which produce acids by their own activity, like the lactic-acid bacilli and acetic-acid bacteria, are sensitive to their products and cannot acidify their soil beyond a certain degree. Like all higher beings, bacteria produce substances as the result of their tissue-change, which, when they accumulate, are injurious to them. In the case of the putrefaction of albuminoids, indol, scatol, and phenol (carbolic acid), substances of distinctly antiseptic properties, are among the terminal products in an amount sufficient to check further bacterial activity. Hence the growth and decomposing activity of micro-organisms cease in many instances before the soil in which they grow is completely decomposed or fully exhausted as food. This self-limitation of bacterial activity does not, however, occur in all instances.

The influence of atmospheric oxygen upon their life and activity has received most attention since Pasteur formulated his view in the striking statement, that "fermentation is life without oxygen." This generalization was founded upon his researches on alcoholic and butyric-acid fermentations, both of which can occur in the absence of all free oxygen. He divided micro-organisms into aërobes, which require oxygen like all higher beings, and anaërobes, which can exist only where free oxygen is absent, and claimed that only the latter class can act as agents of fermentation and putrefaction. Unbiassed investigations, however, by others (Hueppe,[14] Liborius[4]) have shown that Pasteur's generalization is altogether too dogmatic. There exist all gradations of susceptibility to oxygen among different bacteria. The life of some varieties depends upon the presence of free oxygen fully as much as is the case with higher beings, while at the other end of the scale are found bacteria which can grow only when free oxygen is entirely absent. But the majority of bacteria occupy an intermediate position, thriving best in the presence of oxygen, but able to continue their life and activity without it. Pasteur's statement that the fermentations proper can occur only in the absence of oxygen has not been confirmed by others. In the case of putrefaction of albuminoids it has been demonstrated that, while it may occur when free oxygen is absolutely absent, it is then a much slower process than in the presence of oxygen (Jeanneret[5]), and perhaps qualitatively somewhat different (Rosenbach).

Bacterial activity is greatest at a temperature varying from 32° to 40° C., according to the variety of bacteria. Cold retards it, and at between 5° and 10° C. it practically ceases. But extreme cold, as low as can be produced artificially, does not destroy bacteria effectually, only reducing them somewhat in numbers. On the other hand, a temperature of 56°, or at the most 60° C., maintained for at least twenty minutes, kills all bacteria during the period of growth with certainty. If in the dried state, however, they require a temperature of more than 100° C. for their destruction, while the more resistant spores of bacilli can be destroyed only by actual boiling or exposure to live steam during a period varying from three minutes to fully twenty minutes, in extreme instances. Dry heat, in order to be effectual in killing spores, must be maintained at 150° C. for at least three hours. A very reliable method, however, of destroying bacteria wherever resistant spores are present, is by means of discontinuous heating. A temperature of 58° C., or more if applicable, will suffice to kill all developed and growing bacteria, if maintained for a sufficient length of time in proportion to the quantity to be sterilized. The spores which escape uninjured will then begin to germinate, if the soil is kept at a favorable temperature, and in the germinating state they are readily destroyed by a second heating after the lapse of some hours, after which a chance may be given for the development of any spores yet dormant. A mild heating thus repeated from three to five times in the course of as many days can in this manner sterilize any material with certainty.

Exposure to the rays of the sun is unfavorable to the growth of bacteria, and it has even been found that some forms may be killed by twelve hours' insolation in midsummer (Downes and Blunt, Duclaux[6]). These experi-

ments, however, have not yet been varied sufficiently to do justice to the subject.

It has further been learned that rapid motion and agitation of fluids is unfavorable to the growth of bacteria in them (Howarth, Reinke).

Upon our knowledge of the conditions of putrefaction are based the various industrial means of preserving food. Drying the decomposable material is one of the oldest household means; for instance, in the case of fruits and thin slices of meat. In smoking meats we avail ourselves of the antiseptic properties of the creasote of the smoke; while strong brines or vinegar used in preserving articles likewise render the soil unfavorable for the growth of bacteria. Sterilization by heat is made use of in canning meats and vegetables, and the very success of this procedure, carried out on such a vast commercial scale, is but a proof of the accuracy of our knowledge concerning the causes of putrefaction.

A study of different putrefactive processes teaches that the kind of micro-organisms varies with the material and mode of decomposition observed. Each special form of decomposition is due to a specific form of bacteria. Thus the kinds which rot albuminoids are different from the kinds which sour milk or decompose urea, and most of the disease-germs so far studied are found to exert no decomposing influence at all upon the dead soil in which they are cultivated. But there exist, in all probability, a number of varieties which can decompose a given material, though the resulting products may vary quantitatively and qualitatively according to the species causing the decomposition. Thus urea may be transformed into carbonate of ammonia by at least four different kinds of bacteria, and milk-sugar can be changed into lactic acid by two forms of bacilli, and several varieties of micrococci. Indeed, a form which produces a characteristic decomposition of any certain substances need not be chemically inert in relation to other substances. A satisfactory survey of the field is, however, only possible if we take the broad view that there exist numerous varieties of bacteria separate and distinct from each other, each with a given chemical energy peculiar to it. Wherever, therefore, decomposable material is exposed, the variety or varieties of bacteria which can develop in it by reason of their adaptation to the soil, or accidental introduction in overcrowding number, will determine the chemical course of the decomposition. From this point of view we will consider, as fully as is consistent with the plan of this work, the various kinds of putrefactive processes and the biology of the micro-organisms involved.

Decomposition of Albuminoids and other Nitrogenous Tissue Materials.—Of all organic substances the complex nitrogenous materials which constitute the basis of the animal and vegetable tissue are the most readily attacked by putrefactive bacteria. When in the solid state, the albuminoids and related substances are gradually dissolved by the bacteria—probably by the aid of ferments analogous to the pancreatic ferment (trypsine) secreted by the micro-organisms. This action is illustrated by the liquefaction of gelatine and coagulated blood-serum around the colonies of many varieties of bacteria growing on such a culture-soil. The transformation which then occurs resembles chemically the digestion of these substances in the alimentary canal, at least in the earlier stages of putrefaction. Soluble albuminoids are formed, and these in turn are changed into peptones. But as fast as any new product occurs it is further attacked, so that within the first twenty-four hours of active putrefaction a large variety of decomposition products can be detected in variable proportion. As the process continues the amount of the more complex substances diminishes, and those built on a simpler chemical type augment in proportion. As the principal products gradually formed, and in their turn further decomposed, may be mentioned soluble albuminoids, peptones, leucine, sometimes tyrosine, glycocoll, volatile fatty acids, viz., butyric and valerianic (with smaller amounts of acetic) acids, indol (and in traces also scatol and phenol), while the simplest ultimate derivatives are ammonia, sulphuretted hydrogen, and carbonic acid. The offensive smell of rotting material is due to the sulphuretted hydrogen, ammonia, indol, scatol, volatile fatty acids, and presumably traces of other derivatives not yet identified. The chemistry of albuminoid putrefaction cannot be stated in any series of formulæ, since it varies qualitatively, and still more so quantitatively, with the material attacked, the presence of impurities, the temperature, and probably also the species of bacteria involved. Besides the principal products enumerated, smaller quantities of many other compounds occur temporarily in the course of any putrefaction. Of special interest among them are a series of alkaloids, which have been termed *ptomaïnes.* They have recently been studied more thoroughly by Brieger,[7] who has isolated over fifteen alkaloids from different putrid materials, some of which are intensely poisonous to animals, while others are indifferent. These ptomaïnes exist only in small quantities and transiently, being destroyed as the putrefaction proceeds. It is probable that these alkaloids or ptomaïnes are not the only poisonous substances formed by putrefactive bacteria, since at different stages of putrefaction intensely poisonous action can be obtained from extracts of the material made with glycerine and other solvents.

Numerous different forms of bacteria can be found in rotting material. The rôle played by each of the different micro-organisms in putrefaction has not yet been ascertained with certainty. There are probably several varieties of bacilli able to decompose albuminoids. A bacillus has been isolated from the human fæces which in pure culture decomposes albumen, or any of its decomposition products, in the same order as in the usual form of putrefaction (Bienstock). This bacillus is characterized by the transition through different shapes of short and long cells and filaments, and the final formation of terminal spores, giving it the appearance of a drumstick. This form is, perhaps, the most common one found in putrid material. Possibly this shape may pertain to several separate varieties of bacilli, since Hauser[9] has obtained from rotting solutions three bacilli answering to this description, but differing from each other in the rapidity with which they attack albumen. Characteristic, also, of the forms studied by Hauser is their pleomorphism, the cycle of shapes through which they pass in pure culture being made up of elliptic cells, short rods, long rods, filaments, and in some cases screw-shaped spirilla.

Several other micro-organisms have been identified by Rosenbach[10] as the agents of albuminoid putrefaction. Three of them were bacilli, of which one is probably identical with the bacillus found in fæces. A fourth form of microbe was an exceedingly small micrococcus. These bacteria, when tested in the absence of oxygen, were still capable of attacking albumen, only in a much slower and less complete manner than when oxygen was present. It is probable that micrococci and short forms of bacteria (the so-called bacterium termo), found mainly in the upper layer of decaying solutions, play a rôle in the oxidation of the various products formed.

Decomposition of Urea.—Whenever urine collects under favorable conditions of temperature it acquires in the course of some days an ammoniacal odor. This is due to the transformation of urea into bicarbonate of ammonia, by combining with two molecules of water. Although urea undergoes this change readily on boiling in alkaline solution, it will not decompose spontaneously, and urine caught in vessels free of germs retains its composition unaltered. By means of pure cultures, on dry nutritive soil, four varieties of bacteria have been found which can produce the hydration of urea (Leube and Graser[11]). Of these, one was a micrococcus forming chains, and three were different forms of short bacilli. Other bacteria, as far as they have been tested, did not exert such action upon urea. Indeed, urine when allowed to stand will invariably harbor different varieties of micro-organisms, but unless containing one of the specific species of *micrococci* or *bacilli ureæ*, it may become putrid without containing bicarbonate of ammonia.

In consequence of disease of the bladder the urine is sometimes voided already in a state of ammoniacal de-

composition. In such instances bacteria are always found in it, which have been introduced into the bladder by means of impure catheters. But from ammoniacal urine a non-organized ferment has been isolated by means of precipitation with alcohol, which in aqueous solution will gradually transform urea into ammonia carbonate without the further presence of bacteria. Whether this chemical ferment is formed in the first instance by the micro-organisms is as yet an open question, though this is the most plausible view. It could not be obtained, however, by filtering out through porous clay cells the specific bacteria artificially added to normal urine. In the older books an acid fermentation of the freshly voided urine is described. According to later researches (Roehmann [12]) this does not exist, except when the urine contains sugar or alcohol.

DECOMPOSITION OF MILK.—Milk can be obtained from the udder without the admission of micro-organisms, but only on exercising the utmost antiseptic precautions, and even in that case not every attempt is successful (Lister,[13] Cheyne, Meissner [2]). In such successful instances it will remain sweet forever, provided all future access of micro-organism is prevented. Ordinarily, however, milk sours very speedily, its milk-sugar becoming transformed into lactic acid. The curdling of the caseine, which occurs when milk sours, is due to the action of the lactic acid formed, which latter change is always the result of bacterial action. The most common agent of the souring of milk is a very short bacillus, which under a low power of the microscope might be mistaken for an elongated micrococcus, there being usually two cells adherent to each other (Hueppe [14]). This bacillus produces spores which require thorough boiling of the milk for at least thirty-five minutes before they can be destroyed with certainty. Milk-sugar (as well as other varieties of sugar) are split by it into lactic acid and carbonic acid. The lactic acid stops further bacterial action after accumulating to the extent of about 0.8 per cent. In order to obtain lactic acid in quantity, it is therefore necessary to remove the acidity by means of carbonate of calcium. The bacillus just described can act only in the presence of oxygen. But another micro-organism, apparently identical with this one in shape, growth, and action, which has been found in the fæces of nursing infants (Escherich [15]), does possess the ability to acidify milk-sugar even in the absence of oxygen. Possibly this may be but a physiological variety of the first-described bacillus. Another bacillus, not yet sufficiently described, which has been cultivated from the fæces of adults (Bienstock [8]), decomposes milk-sugar into lactic acid and alcohol. Milk can also be soured by the various micrococci found in pus, as well as by the micro-organisms of erysipelas and pneumonia.

Lactic acid is transformed into *butyric acid* by certain forms of very large bacilli. They cannot, however, attack the original milk-sugar unaided by the lactic-acid bacteria. Their spores are killed with some difficulty in milk, so that, when a number of samples are sterilized by boiling, it sometimes happens that the butyric-acid bacilli escape destruction. In such cases the milk curdles subsequently without souring, because these bacilli secrete a ferment of similar action to rennet, which coagulates the caseine. The curdled caseine is later redissolved by the same bacilli, and changed into peptone with the formation of some bitter product (Hueppe). The bacilli can transform lactic acid and lactates (as well as some other organic salts) into butyric-acid, with the liberation of small quantities of butyl alcohol (Fitz [16]). The flavor of matured cheeses and milk beverages, like koumiss and kephir, is the result of their action.

The butyric-acid bacilli have been separated into three varieties, distinct from each other, by cultivation on dry soil in a vacuum (Gruber [17]). Of these varieties two are strictly anaërobic, and cannot act except in the absence of oxygen; while the third form, though able to dispense with oxygen, thrives best when supplied with it.

Cellulose can be dissolved and decomposed by a large bacillus found in the mud of swamps, and also by an undescribed micro-organism occurring in the intestines of cattle. It is split into carbonic acid and carburetted hydrogen (CH_4), or, in alkaline solutions, into carbonic acid and free hydrogen. It is probable that the disappearance of the ingested cellulose in the digestive tract of herbivora is entirely the work of micro-organisms (Tappeiner [18]).

The turning rancid of fats, whereby they are partly decomposed into free fatty acid and glycerine—which latter undergoes further change into ill-smelling products, yet insufficiently examined—is not the result of bacterial action. Although this process resembles putrefaction in the conditions by which it is influenced, no characteristic bacteria could be recognized by the microscope or culture methods in some unpublished experiments made by the writer with Mr. Hoskins. It was likewise found impossible to hasten the rancidity of fresh fats by infection with rancid samples. Duclaux [19] has since arrived at similar results, and has referred this change to oxidation.

The *alcoholic fermentation* is ordinarily produced by yeast-cells, although some bacteria have been found which can likewise form alcohol (Bienstock [8], Fitz [16]). Whenever this fermentation occurs at a high temperature, as in the distilleries, it is complicated by the presence of different forms of bacteria—lactic- and butyric-acid bacilli and others—which interfere with the work of the yeast quantitatively, besides producing products of their own which give an unpleasant flavor to the spirits. In observations made in a distillery by the writer, with the late Mr. Woltmann, it was found feasible to increase the yield of alcohol and improve the flavor of the product by employing pure cultures of yeast, and excluding bacteria as far as possible.

The acetic acid fermentation of alcohol is due to a micro-organism growing in the form of chains, which has not been studied morphologically to a sufficient extent, and of which it is uncertain whether it is a large micrococcus or a short bacillus. It oxidizes the alcohol into vinegar, and hence requires free access of oxygen for its action (Pasteur).

Hygienic Aspects of Putrefaction.—Medical interest is deeply concerned in all putrefactive processes, in relation both to the biology of the micro-organisms and to the chemical or poisonous properties of their products. Some of our articles of diet are consumed in a state of partial decomposition. For instance, most cheeses have passed through a lactic- and butyric-acid fermentation, while in some favorite brands actual putrefaction has occurred, as the smell plainly indicates. The gamy flavor, or "haut goût" of meat, demanded by epicures, proves its commencing decomposition, while in many other instances it is placed on the table strongly tainted in the warm season, not intentionally, but from want of care in its preservation. But no harm results ordinarily from the use of such articles. Instances, however, do occur where families, or even communities, are poisoned by the consumption of cheese or meats, especially fish and sausages. The symptoms are those of intestinal irritation, vomiting, nausea, diarrhœa; furthermore, prostration and generally marked dryness of the throat. It is yet an open question whether the articles causing such wholesale poisoning must be eaten while in a particular stage of putrefaction, or whether their decomposition in such cases is due to some specific form of bacteria different from the ordinary agents of putrefaction, and capable of forming poisonous products peculiar to themselves.

The latter view is the more probable one, since in such instances of poisoning the food does not generally indicate decomposition by its smell and appearance. The rapid onset of the poisoning, and its short duration in cases of recovery, suggest that it can only be the effect of a chemical poison, and not an infection due to the entrance of bacteria into the system, at least in most of the instances reported. In a case of sausage-poisoning Ehrenberg [20] found the usual decomposition derivatives of albumen, including some of the less poisonous ptomaïnes, but still he could not detect the special poison to which the observed effects were to be attributed. He isolated a bacillus from the sausage, capable of decomposing albu-

men, but our information is not precise enough to say whether this was one of the common forms of putrefactive bacteria or not. In an instance of poisoning from dried beef (in Momence, Ill.) the writer found in different samples of the meat, alternately, a micrococcus and a short bacillus present in large numbers, which differed morphologically from the organisms found in ordinary putrid material. The meat did not appear tainted. From cheese which had poisoned a large number of persons, and later on, also, from poisonous ice-cream, Vaughan[21] has isolated a substance which he terms tyrotoxicon, and which possesses the characteristic poisonous action as tested upon man. He is inclined to consider this substance identical with diazobenzol.

On considering the hygienic relation of putrefaction, it must not be forgotten that this process occurs normally in the intestines below the stomach. In the mouth of all individuals there exist a very large number of micro-organisms, many of which are capable of causing putrefactive and fermentative changes in food (Miller[22]). While the conditions in the mouth permit them to multiply to some extent, they find no material to attack except in hollow teeth, or between the teeth and receding gums, and in such cases their action reveals itself in the tainted breath. It can hardly be expected that these parasites are always harmless, although we do not yet know fully their etiological significance.

The hydrochloric acid of the gastric juice has sufficient antiseptic power to kill all developed bacteria, if present to the extent of over 0.16 per cent., but it cannot injure spores. Hydrochloric acid, however, does not occur in an empty stomach, is not secreted within the first few minutes of digestion, and does not reach the necessary limit of 0.16 per cent. until about half an hour after meals, so that there is plenty of opportunity for bacteria to pass through the stomach alive. Moreover, particles of food shelter them somewhat even during digestion (Miller). Below the point of entrance of the bile and pancreatic juice into the duodenum, bacteria find the suitable alkaline or, at least, very faintly acid reaction, and here their work begins. Chemically, their activity reveals itself in the production of substances which cannot be formed by the action of the digestive ferments in the absence of bacteria—like indol, scatol, phenol, sulphuretted hydrogen, and the volatile fatty acids. Normal human fæces consist microscopically of scarcely anything but bacteria, except when a vegetable diet adds its undissolved residue. It is not known whether the normal intestinal bacteria are of any real service in digestion, but their invariable presence indicates that they are harmless to the individual under ordinary circumstances. But whether poisonous decomposition-products may not be formed and absorbed under some conditions—in intestinal obstruction—is an open question. It has been found that among the human intestinal parasites there occur some forms (Bienstock, Brieger[23]) pathogenic to small rodents.

The occurrence of putrefactive processes in surgical practice was the first incentive to Lister in his earliest attempts at antiseptic surgery. At that time (1867) it had not yet been proved that the traumatic infectious diseases were due to parasites, but it was evident in surgical practice that the decomposition of pus and other secretions exerted an injurious influence upon wounds. It has since been demonstrated, step by step, by the injection of putrid material into the bodies of animals, by Weber, Billroth, Panum, and others, by the bacteriological examination of Rosenbach on patients, and especially by the magnificent results of improved antiseptic surgery, that the systemic complications of wounds, ranging from the milder forms of traumatic fever to fatal septicæmic blood-poisoning, are the result of the absorption of decomposition-products of bacteria. A broad distinction must be recognized between actual surgical infection, where parasitic micro-organisms are growing in the tissues—as, for instance, in erysipelas and pyæmia (metastatic abscesses)—and putrid poisoning, in which the bacteria exist only outside of the tissues, in the fluids or necrotic parts of the wound, from which regions their chemical products are absorbed. The bacteria which can, in the latter case, poison the system may be the common forms of putrefaction, which do not possess the power of penetrating into the tissues. Quite often, abscesses with foul-smelling contents harbor putrefactive bacilli, together with the specific micrococci causing the suppuration. It is evident that those instances of septicæmia in which the cause is outside of the body offer an entirely different prognosis from actual infections, in which the surgeon's knife and antiseptic drugs cannot follow the bacteria into the tissues.

Rotting material accumulating around dwellings, the refuse of the kitchen, and the contents of cesspools have always been regarded with anxiety by sanitarians. It is doubtful, however, whether any poisonous products existing there can in any way affect us. The foul gases —ammonia and sulphuretted hydrogen—though known to be poisonous, are not generated in sufficient amounts under ordinary circumstances to cause acute poisoning, while chronic poisoning from these gases has not yet been observed or, at least, recognized. The more serious aspect of such collecting filth is the possibility of its harboring pathogenic bacteria, for the organic material which forms a nutritive soil for putrefactive bacteria may also serve as food for occasional parasitic and pathogenic forms which find their way into it. It is probable that in this way, and only thus, filth plays a rôle in the spread of some infectious diseases—for instance, typhoid fever and cholera.

Putrefactive processes play a rôle in the household of nature, and particularly in relation to agriculture, the magnitude of which has only been suspected lately. The surface soil, wherever it contains organic remnants and is suitably moist and warm, teems with bacterial life. Over half a million of germs (in an extreme case up to forty-five millions) have been found in a gramme of different soils. At a distance of several feet from the surface the vegetation of micro-organisms ceases ordinarily (Koch), though in some instances of contaminated soils they have been found as low as eighteen feet below ground (Beumer[24]). As far as the bacteria penetrate into the soil, they alter its chemical composition continuously during the warm season.

Two classes of processes occur in the ground : on the one hand, the ordinary putrefaction of organic remnants, resulting in their decomposition, and, on the other hand, a slow oxidation of organic substances. The latter change can be measured by means of the carbonic acid evolved (Wollny[25]). A study of the conditions influencing this oxidation shows it to be due to bacterial action, although the forms causing it have not been identified. This oxidizing process plays undoubtedly a considerable rôle in the removal of organic remnants from the surface of the earth, since none of the characteristic smells of putrefaction is noticeable in fields and forests, at least outside of marshy parts, although the residue of the last season's vegetation disappears annually. It is not exaggerating the importance of these processes to assert that it is only through their instrumentality that plant life is possible on the surface of the earth ; for higher plants are not able to assimilate nitrogen from the soil except it be present in the form of very simple compounds—ammoniacal salts and nitrates. It is only through the activity of the bacteria that the residue of previous vegetation or of animal bodies can serve as food for subsequent vegetation.

Historical Bibliography.—Putrefaction was a favorite theme with the older medical and chemical writers, but was discussed by them only in a speculative manner. In 1837 it was first shown, by Schwann, that putrefaction and fermentation were due to the action of micro-organisms, and this view was later on confirmed by Schroeder and Dusch. To Pasteur's ingenuity, however, we owe most of our positive knowledge concerning the actual conditions of these processes, and this brilliant investigator has shown a rare perseverance in his studies of that subject. Passing from alcoholic fermentation to putrefaction, he took up in turn lactic- and butyric-acid fermentation, and the various changes which caused the

spoiling of wine and beer. His results, published in the *Annales de Chimie et Physique*, 1860 and 1862, and also in various proceedings of the French Academy of Sciences (Comptes Rendus), are collected to some extent in his separate work, "Etude sur la Bière," 1876 (English edition by Faulkner & Robb, "Studies on Fermentation," 1879). The history of the earlier studies on putrefaction can be found in Watson Cheyne's "Antiseptic Surgery," 1882, and in Gradle's "Bacteria, and Germ Theory of Disease," 1883.

Further studies in the biology of putrefactive bacteria have been published by Bienstock[8] and Hauser.[9] But we still lack any complete classification of the different forms of micro-organisms concerned in these processes. The decomposition of milk has been thoroughly investigated by Hueppe.[14] The chemical side of putrefaction has been most advanced by the labors of Nencki ("Ueber die Zersetzungen d. Gelatine u. d. Eiweiss bei der Fäulniss mit Pancreas," Bern, 1876), while the most painstaking work has been bestowed by Brieger[7] on the separation and identification of the alkaloidal ptomaïnes.

The sanitary, and especially the pathological, aspects of putrefaction have been fully discussed, up to 1879, by Hiller, in his "Lehre von der Fäulniss." The most complete compilation of the bacteriological side of the subject can be found in Fluegge's "Fermente und Microparasiten" ("Ziemssen's Handbuch der Hygiene," 1st ed., 1883, and 2d ed., 1887). *H. PYLORUS, RESECTION OF; PYLORECTOMY. The operation for the removal of the diseased (usually cancerous) pylorus is the legitimate outcome, on the one hand, of the recent progress of surgery as based on physiological and pathological studies, and, on the other, of an increasing boldness—begotten of success—in operative attacks upon the digestive tube. Among these latter we may mention gastrotomy, gastrostomy, and resection of varying lengths of the pharynx, œsophagus, and intestine. In fact, scarcely any portion of the alimentary tract has been exempt from the surgeon's knife. Twenty years ago, indeed, Torelli excised a considerable portion of the stomach-wall, which, with two penetrating wounds within its limits, had prolapsed from an incised abdominal wound; his patient recovered and lived for many years. This was possibly the first stomach-resection, though not a resection of the pylorus.

Induced thereto by previous surgical exploits, several workers began experimenting upon animals. Merrem, in 1870; Gussenbauer and Winiwarter, in 1876; and Czerny, in 1878, had made it clear that a partial, even an *entire*, resection of the stomach could be made upon dogs, and with success. All this having been demonstrated, it needed only a surgeon with sufficient boldness, and a willing patient, for a practical test of the feasibility of the operation in the human subject. In 1877, Billroth asserted that there was no reason why the operation should not succeed; in 1879 he went further, and said that it *must* succeed; but it was reserved for Péan, of Paris, to make the first essay. In April, 1879, he yielded to a positive demand for relief on the part of a patient with cancer of the pylorus. This patient died five days later of inanition, after two blood-transfusions. In November of 1880, Rydygier, of Kulm, made the second operation, his patient dying twelve days later of collapse.

Three months later Billroth reported a third case, the first successful one. His patient made a brilliant recovery, but died at the end of four months in consequence of a return of the disease.

INDICATIONS.—We may hold that resection of the pylorus is indicated in:

1. Irritable and intractable pyloric ulcer, leading to spasmodic stenosis.
2. Simple fibrous or cicatricial stenosis.
3. Circumscribed cancer, without adhesions to the pancreas or spleen.

By a legitimate extension of our limited subject we may further say that resection, either of the pylorus or of any other part of the stomach, would be indicated in:

4. Hæmorrhage from ordinary gastric ulcers, by which life was threatened.
5. Perforation of a gastric ulcer.
6. Gunshot or stab wound, if ragged or irregular.
7. Hernia of the stomach complicated with any of the above conditions.

1 and 2. Ordinarily, ulceration of the stomach does not become so aggravated as to call for operative interference, but when the symptoms dependent thereon pass endurance, or when, the active process having subsided, the lesions are succeeded by stenosis, so that the patient must be fed by enema or starve, then drugs can give no relief. It is in cases of this class, though few in number, that the operation has been brilliantly successful, five patients out of eight having been cured. In cases included under the second indication, the resection-method, to be sure, has now to compete with Loretta's method by digital divulsion; of the former it may be said that even if it be the more dangerous (though not much more so) it is the more effective.

3. It is in cases of cancer that this operation has been most frequently resorted to. It is worthy of especial note that the pylorus is by far the most common seat of cancerous disease of the stomach. Gussenbauer and Winiwarter investigated the records of the Vienna Pathological Institute, embracing a period of fifty-six years. Out of 61,287 autopsies, cancer of the stomach was found 903 times. In 542 of these the disease involved the pylorus. In 223 of the 542 cases no metastatic deposits could be found, and in 172 of them the tumor was found to be non-adherent, *i.e.*, in a condition most favorable for operation. Moreover, Rokitansky's observation, that cancer of the pylorus rarely involves the duodenum, is worth remembering in this connection.

Obviously the matter of diagnosis is one of prime importance. It is not merely the question of malignancy that is to be decided, but also that of the extent of the disease and of adhesions to the neighboring viscera. An uncomplicated case is one favorable for operation; on the other hand, involvement of the peritoneum, liver, or mesenteric glands, and firm adhesions to the colon or pancreas, make it most unadvisable. The experiments of Rydygier and Senn have shown that a piece of the pancreas may be removed with success, provided its duct be not occluded; but the difficulty of effecting this in a living patient would deter most men from the attempt. It is true, also, that a portion of the mesentery or of the colon may be excised, but the operation is thereby the more prolonged and complicated. For the symptoms and diagnosis we must refer the reader to the appropriate heading (see Stomach, Organic Diseases of). To illustrate the difficulty of diagnosis in these cases, the writer would adduce the case in which Billroth and Bamberger having

both diagnosed cancer of the pylorus, the former operated and found an anomaly of the kidney.

At all events, there can be no objection, in a case of proposed pylorectomy, to perform a diagnostitial laparotomy, limiting the operation to this in case the conditions thereby revealed make it improper to proceed. This has been done a number of times without giving occasion for regret.

4 and 5. These indications are theoretical rather than founded on experience; yet a moment's reflection will show that they are not chimerical.

6 and 7. That these indications are of practical bearing the case of Torelli, quoted above, and various recent experiences and studies fully demonstrate.

Preparation for Operation.—The absence of any very unfavorable symptoms having led to a determination to operate, the patient should be carefully prepared for th · ordeal. To this end the diet,

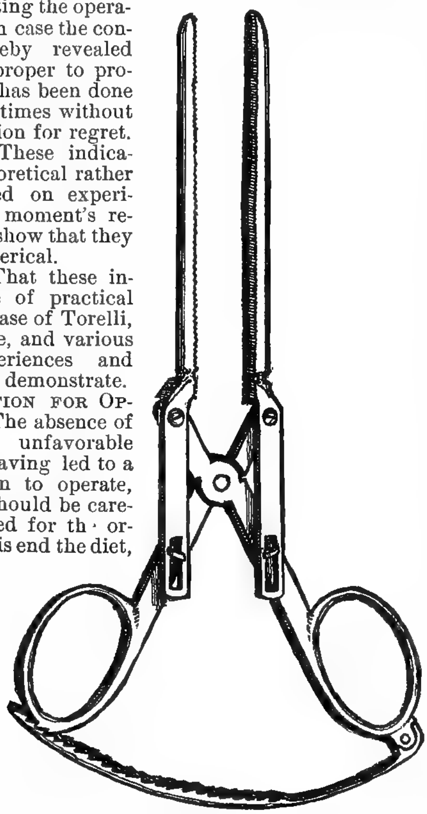

Fig. 3215.—Rydygier's Clamp, with Parallel Blades. The blades are covered with rubber tubing.

doubtless already restricted, must be simplified or reduced to milk only. The stomach should be washed out daily once or oftener, and in case the gastric symptoms have been very distressing the better way would be to feed by nutritive enemata and to frequently cleanse the stomach. Careful attention must also be given to the bowels, and, in fact, no precaution which careful laparotomists adopt should be omitted.

Operation.—Hitherto an anæsthetic has always been administered, preferably chloroform. This should be preceded by a full

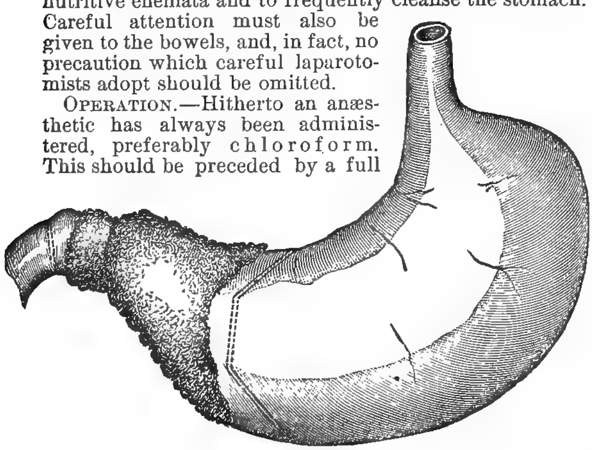

Fig. 3216.—Cancer of Pylorus. Lines indicating shape of exsected portion.

hypodermic dose of morphine. The stomach should always be washed out with a weak salicylic solution, as a preliminary to the operation, either before or just after the anæsthetic. A recent experience which the writer has enjoyed leads him to think that, after inducing a mild morphine-narcosis, cocaine used hypodermically and locally might suffice. Working thus with cocaine alone, he has been able to make a successful gastrostomy without anything more than some slight local discomfort.

By some operators the incision in the linea alba has been preferred; some have made it parallel to the left costal cartilages, others parallel to those on

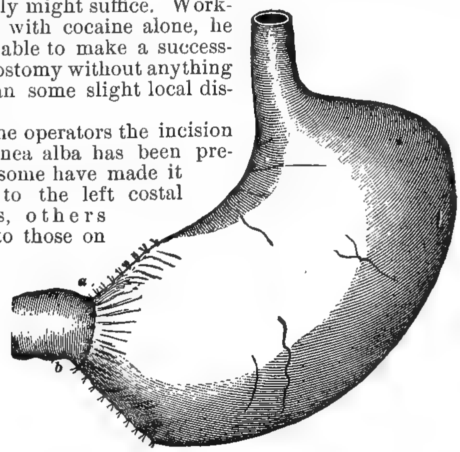

Fig. 3217.—Cancer of Pylorus. Same case as above, showing lines of suture.

the right side. An opening by which one or both recti may be severed has its obvious disadvantages, while for some of the cases the median incision would not give sufficient room. The best rule is to let the exact location and size of the internal tumor determine where and in what direction to cut.

The tumor having been cut

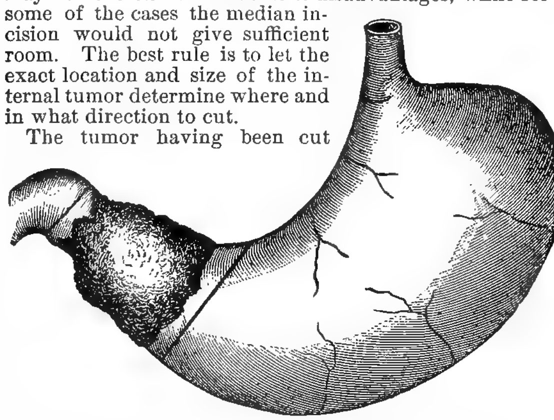

Fig. 3218.—Cancer of Pylorus. Showing portion to be removed.

down upon and exposed, as are other abdominal tumors, the surgeon must first convince himself that no contra-indications exist, especially in the way of secondary affection of the pancreas, liver, gall-bladder, or inaccessible mesenteric glands. Being satisfied in these respects, he should then draw the tumor as far forward as is judicious, and begin the task of separating it from its surroundings. These are

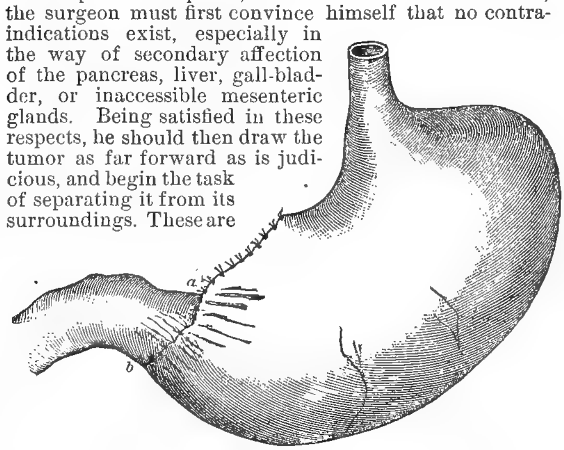

Fig. 3219.—Cancer of Pylorus. Same case as that represented in Fig. 3218. Showing lines of suture.

particularly the gastro-colic ligament and the lesser omentum. These must be separated from the pyloric region for a sufficient distance to permit the removal of the dis-

eased mass, and no farther. This is effected by including small portions between double ligatures and then dividing with the thermo-cautery. This part of the operation must be done with great care. A large sponge

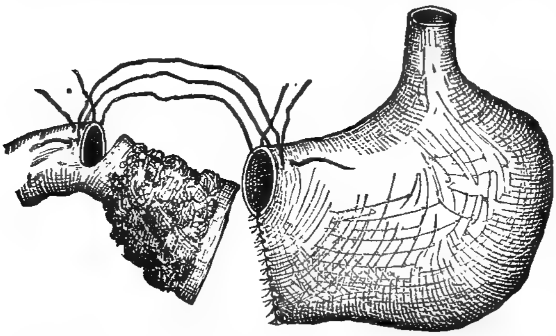

FIG. 3220.—Illustrating Technique. Placing a few retaining sutures before complete exsection.

is now passed under the tumor-mass, to isolate it from the rest of the abdominal contents. A couple of clamped forceps, or their equivalents, are lightly passed on either side of the tumor, to prevent regurgitation of gastric or intestinal contents; or, instead of these, the fingers of an intelligent assistant can be made to do the work as well or better.

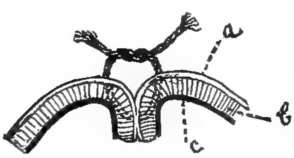

FIG. 3221.—Lembert's Suture. *a, b, c,* Peritoneal, muscular, and mucous coats.

The excision of the cancerous mass is now to be undertaken. The lines of incision must be made according to the size and relations of the tumor. The accompanying cuts (Figs. 3216, 3218, and 3220), from Woelfler's monograph, show what portions were removed from three of Billroth's cases. In other cases the exact shape of the excised portion has been different. The endeavor should be to hold the stomach completely flat, so that pieces of exactly the same shape may be removed from its posterior as from its anterior wall. Numerous small vessels in the gastric and duodenal walls will be found to bleed freely. Upon as many as require it ligatures of catgut may be placed. Hæmorrhage having been quieted, the operator at once addresses himself to the union of the divided parts.

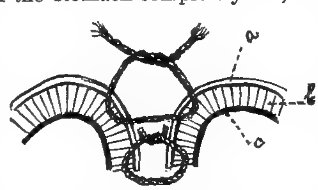

FIG. 3222.—Czerny's Suture. *a, b, c,* Peritoneal, muscular, and mucous coats.

The question now comes up concerning the best of the several intestinal sutures that have been devised. The inherent differences between the commoner and more preferable varieties can be better recognized by reference to Figs. 3221, 3222, 3223, 3224, than by verbal description. Lembert's suture takes in both the serous and the muscular coats. Czerny improved this by an additional separate stitch through the mucosa. Gussenbauer still further improved it by combining the two stitches in one act, and it is his method which we recommend. Special care must be given to coaptation, and in certain cases it may be well to place some of the stitches before the mass is completely excised, as is shown in Fig. 3220. Above all, too much caution cannot be exercised in closing the angles marked *a* and *b* in the cuts, Figs. 3217 and 3219. Should there be a doubt as to the security of the closure, it would be better to run another series of fine sutures partially or completely around.

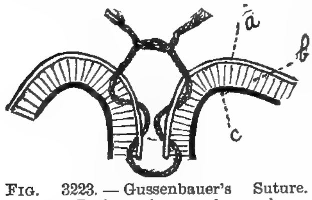

FIG. 3223. — Gussenbauer's Suture. *a, b, c,* Peritoneal, muscular, and mucous coats.

Something must be said concerning the choice of needles and suture-materials. The former must be round in transverse outline—*i.e.*, without cutting edges—small and straight, barely large enough to hold fine silk or catgut. For suture-material we recommend Chinese silk which has been carefully disinfected. It is much stronger than catgut of the same size, and is not so soon absorbed. Fine catgut may answer well for the ligatures, but silk is certainly preferable for the sutures.

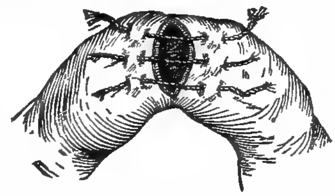

FIG. 3224.—Lembert's Suture. Applied to a small wound.

The tedious process of inserting all the necessary sutures having been completed, the clamps are removed, any toilette of the peritoneum that may be called for is made, the parts are dropped back, and the abdominal wound is closed *secundum artem.* To briefly describe the operation does not take long, but to properly perform it may consume from one and a half to three hours. It calls as much for extreme patience on the part of the operator as for skill in technique.

The patient is now to be treated as after any abdominal section, save that nothing but cracked ice, in minimum quantity, must be allowed in the mouth for from forty-eight to seventy-two hours. After this, feeding by the mouth may be attempted with scrupulous care. For the first few days feeding must be done mainly by the rectum. Every effort to prevent vomiting must be practised.

RESULTS.—While referring the interested reader to the special literature for detailed statistics of cases, we may say here that of seventy cases now on record, pylorectomy has been done sixty-two times for cancer, with thirty-five deaths (57%), and eight times for stenosis, with three deaths (37.5%). Considering that every one of these cases had that about it which made it inherently fatal, the operation seems to have been sufficiently successful to justify its performance in select cases. *Roswell Park.*

PYRMONT is situated in the principality of Waldeck-Pyrmont, in Germany, at an elevation of about four hundred feet above sea-level. There are a number of iron and saline medicinal springs in the place, the best known of which are the Stahlquelle, Brodelbrunnen, and Helenenquelle among the iron springs, and the Salztrinkquelle, Badequelle, and Bohrlochsoole among the saline.

The following are the analyses of these three iron springs, expressed in grammes per litre. One litre contains:

	Stahl-quelle.	Brodel-brunnen.	Helenen-quelle.
Bicarbonate of iron	0.077	0.036	0.074
Bicarbonate of manganese	0.006	0.003	0.007
Bicarbonate of calcium	1.046	1.003	1.246
Bicarbonate of magnesium	0.080	0.076	0.012
Chloride of sodium	0.158	0.174	0.181
Sulphate of sodium	0.041	0.036	0.043
Sulphate of potassium	0.016	0.015	0.016
Sulphate of magnesium	0.453	0.492	0.604
Sulphate of calcium	0.792	0.980	0.866
Organic matter, etc	0.044	0.043	0.052
Total solids	2.713	2.858	3.101

There is considerable free carbonic-acid gas in the waters of all these springs. Of the salt springs but one is used for drinking purposes. The analysis of this, the Salztrinkquelle, is as follows: One litre contains, of

	Gms.
Chloride of sodium	7.057
Chloride of lithium	0.006
Sulphate of sodium	0.120
Sulphate of magnesium	0.969
Sulphate of calcium	0.805
Bicarbonate of calcium	1.688
Bicarbonate of magnesium	0.024
Organic matter, etc	0.031
Total solids	10.700

The amount of free carbonic-acid gas is less than is found in the chalybeate springs.

The other saline waters are not drunk, but are used for bathing. A course of treatment at Pyrmont is especially useful in those cases in which both chalybeate and saline waters are indicated, such as various scrofulous and nervous affections, diseases of the female sexual organs, catarrhal conditions, and diseases of the digestive organs, combined with anæmia and debility.

The season at Pyrmont is from the middle of May to the middle of October. In addition to the use of the waters, there are facilities for the various forms of "cures," goat's-milk, whey, pine-needle, etc., so popular at many of the German spas. *T. L. S.*

PYROGALLIC ACID. "Pyrogallic acid" is the name in common use for the phenol *pyrogallol*, $C_6H_3(OH)_3$. This body is producible by the action of heat on gallic acid, whence the name "pyrogallic acid." Pyrogallic acid presents itself in long, flattened prisms; colorless; bitter to taste; soluble in two and a half parts of water, in alcohol, and in ether. In solution, exposed, the acid oxidizes, turning brown. Pyrogallic acid possesses the poisonous property, more or less common to the group of phenols, of affecting the blood and bringing about hæmoglobinuria. Administered by injection to rabbits, this medicine has speedily caused chill, dyspnœa, tremor of the extremities coming on in paroxysms, and death. The urine in such cases has shown the characteristic features of hæmoglobinuria, and the blood has exhibited discoloration and destruction of the red blood-corpuscles. In rapidly produced death by large doses, the blood has turned black or, in some cases, of a chocolate color and jelly-like consistence. In the human subject death has resulted, in one instance, from the application, to one-half the body at once, of a ten per cent. pyrogallic-acid ointment. In this case a violent chill, with vomiting and collapse, set in six hours after making the application of the salve. The patient rallied, but forty hours later a second attack ensued, ending in coma, with great reduction of temperature. Death occurred on the fourth day. During the illness the urine was much diminished in quantity, and showed, in highest degree, the condition of hæmoglobinuria, being dark-brown in color and, upon standing, depositing a thick sediment of amorphous, blackish material. The blood was found, post mortem, disintegrated, and the kidneys bluish-black and stuffed with the same material as the urinary sediment. Pyrogallic acid has been used in medicine almost exclusively as a local application for the relief of certain skin diseases, notably *psoriasis*—an application often successful when other remedies may have failed. Applied in solution or in ointment, pyrogallic acid stains the skin somewhat, but the stain speedily disappears. Linen clothing, however, may be permanently injured by the action of the medicine. To avoid this latter effect, a solution of pyrogallic acid in flexible collodion has been proposed (Elliot). Such preparation, when dried to a film upon the skin, seems still to exert the therapeutic action of the medicine, but, being dried, is without action upon the clothing. Pyrogallic acid may be applied in ointment or in solution, and strengths are used ranging from five to fifteen per cent. of the remedy. The higher percentages, in ointment certainly, may irritate severely, and should be used with caution. Applications should never be extensive at any one sitting, for fear of enough absorption occurring to bring about constitutional poisoning. *Edward Curtis.*

QUARANTINE. The ancients during periods of epidemic pestilence sacrificed to their gods or consulted the oracles on the best means of appeasing the offended deities, and in Christian times fasting and prayer have been undertaken as a means of preservation from these "visitations of Providence." But so long ago as the time of Hippocrates more appreciative views of the origin of epidemics were entertained, for that enlightened authority combated pestilence in Athens and other Grecian towns by directing the citizens to keep great fires burning in the streets, and feed them with herbs and drugs of sweet odor. This implied a recognition of that subtile atmospheric cause which even now exists in many lay and some professional minds, finding expression in the phrase *epidemic constitution.* The doctrine of contagion in relation to these diseases appears to have been developed slowly and almost insensibly, for although Livy speaks of the Roman citizens shutting themselves up in their houses and paying attention to nothing except how to preserve themselves from the pestilence, the time of Boccaccio was reached before systematic efforts were made to exclude contagion from a community. The epidemic which the former describes, devastated Rome B.C. 459, destroying most of the slaves, half of the citizens, many senators, tribunes, and priests, and two successive consuls. The latter refers in his tales to the attempt made by Florence to preserve her citizens from the plague which overspread Europe in 1348, by denying access to all sick persons.

When contagion was recognized in these epidemics—and probably most of them were, from the stand-point of to-day, either directly or indirectly infectious—a grand advance in preservative methods became possible. All European nations enforced laws for limiting the spread of leprosy, and these, which had been handed down from ancient times, had merely to be modified in their application in order to exercise a controlling influence on the spread of fulminant febrile diseases. The sanitary laws of Moses provided for the segregation of lepers and the fumigation and destruction of infected clothing. Among the Gentile nations these unfortunates were also ostracized; they gathered in small communities in the outskirts of cities, and ultimately hospitals were built for them. Even at the present day the spread of leprosy is controlled in the same way. In the Sandwich Islands, where two per cent. of the population is affected, the isolation of the disease to special settlements has been enforced since 1865, for contagion is acknowledged, and every leper, whether in the advanced or incipient stage, is looked upon as a dangerous focus of the malady.

When, therefore, contagion was appreciated as a factor in the propagation of wide-spread pestilential epidemics, the attempt to exclude it, as at Florence, naturally followed. Sanitary cordons were drawn around healthy places to preserve them, and around infected places to prevent the spread of their pestilence. Infected persons were taken out of the city into the fields, there to die or recover, and their attendants were forbidden to associate with anyone for ten days. Ultimately it became recognized that these epidemic diseases had their origin in the East—in Asia, Turkey, or Egypt—and entered Europe by the Mediterranean seaports. Hence, in periods of freedom from pestilence, restrictive measures were concentrated at these ports to prevent its introduction. Venice at that time was the commercial metropolis of the world. Her vessels brought the products of the East to the Western nations, and among them, occasionally, the plague. A lazaretto was built for the isolation and treatment of infected sailors as early as 1423, but not until about 1484 were laws enacted requiring every vessel from suspected localities to undergo a period of detention and observation prior to the admission of her crew, passengers, or cargo. As this period embraced forty days, the term *quarantine* came to be applied to it and all matters pertaining to it. Lazarettos and quarantine codes were afterward established at other exposed seaports, as at Malta, Ancona, Messina, Leghorn, Genoa, Trieste, Marseilles, etc. As the accommodation for suspects was generally insufficient at these quarantine stations, much hardship was inflicted during the period of probation. The full operation of the system was required only occasionally, in times of emergency, and as it was rarely equal to the occasion, extemporizations were necessitated; but these did little to mitigate the evils of the enforced detention of healthy persons in dangerous proximity to those who were infected. Thus quarantine, to its victims, appeared imbued with a spirit of inhumanity, cruelty, and reckless tyranny; and although its methods at the present time are wholly changed, much of the barbarism

of former years continues associated with the use of the term.

Unfortunately the seaport quarantines, no matter how rigorously enforced, frequently failed in their efforts to exclude the plague and prevent its spread into the interior. In this event, sanitary cordons became the established method of limiting the progress of the pestilence—they constituted, in fact, a species of inland quarantine; and, even at the present day, the panic occasioned by an extended prevalence of a deadly epidemic not infrequently calls into existence a vigorous but unnecessary policy of non-intercourse, known in Europe as the *cordon militaire*, and in this country as the *shot-gun* quarantine.

Improvements in the sanitary condition of Europe, consequent on the progress of modern civilization, have succeeded in preventing those terrible visitations of the plague against which quarantine was first instituted. London has not suffered since 1665, and although certain sections specially exposed to infection from the East, as Egypt, Turkey, Malta, Italy, and Spain, have been visited during the present century, the disease is now mainly confined within the Asiatic boundary and seldom threatens the invasion of Europe. But the necessity for quarantine did not cease on the subsidence of this disease, for yellow fever from the West Indies and certain parts of tropical America occasionally ravaged the seaports of Southwestern Europe, and more recently cholera from India has spread epidemically in the pathways of commerce. The former was first imported into Spain from Havana in 1741; but its appearance on European soil exercised no modifying influence on quarantine measures—those in use against the plague were applied for the exclusion of this new exotic. The latter made its first progress through Europe in 1830; and as its westward track from its origin in India was well recognized, the quarantines at the Mediterranean ports became considerably relieved and Western civilization protected by the establishment of special quarantine stations for the interception of the disease in the Red Sea and at points on the overland route.

About this time the severity of the requirements of quarantine became lessened. The natural history of epidemic disease was better known, and instead of an arbitrary detention of so many days the period became based on that of the incubation of the disease to be excluded. Thus in France, in 1847, vessels from infected ports in Turkey and Egypt were admitted without restraint, if ten days had been consumed in the voyage and no disease had appeared on board in the meantime. An imperial decree, in 1853, admitted such vessels at once into the Atlantic ports of France, and into the Mediterranean ports if eight days had elapsed since leaving the port of departure. Steamers from Alexandria to Marseilles landed their mails at once, however short the voyage, but passengers were detained until the period of eight days had passed. Vessels from infected ports were quarantined for ten days after arrival at any of the ports of the empire, and their cargoes for ten days after their removal at the quarantine station. These regulations had regard to plague. With respect to cholera, vessels from infected ports were, in the Mediterranean, subjected to a quarantine of five days including the voyage, and in the Atlantic ports to one of three to five days when one or more cases of the disease had occurred on the voyage; but no quarantine was imposed on the cargo. Vessels from places infected with yellow fever were quarantined from three to seven days at the Mediterranean ports, but had free entry on the Atlantic coast if no sickness or death had occurred during the last ten days of the voyage.

In this country quarantine was instituted against yellow fever from Barbadoes, and typhus and small-pox from the other side of the Atlantic. Philadelphia suffered from the Barbadoes distemper in 1699, and in the following year the Province of Pennsylvania endeavored to secure protection in the future by passing an "Act to prevent sickly vessels from coming into this Government," which required, under penalty of one hundred pounds, that such vessels should come no nearer than one mile to any of the towns or ports of the province, nor land goods or passengers until they had received a license from the proper authorities. Massachusetts enacted a quarantine law in 1701 against vessels infected with plague, small-pox, pestilent or malignant fever, or other contagious disease, or coming from places where such maladies prevailed, prohibiting all communication between the infected or suspected vessels and the shore. In 1758 the colonial legislature established quarantine at New York by an act to prevent the bringing in and spreading of infectious diseases in the colony. After the successful passage of the Atlantic by cholera in 1832, this disease became added to the list of exotic pestilences which it was the object of quarantine to exclude.

Based originally on the theory of contagion, quarantine measures were directed to the detection and isolation of infected individuals, but the transmission of disease by fomites placed restrictions also upon goods, particularly such as experience had shown to be efficient carriers of the morbific matter. This interference with the liberty of the individual, combined with the financial interests involved, raised a continued opposition to quarantine detention, which became more outspoken on every fresh demonstration of the inability of this measure to accomplish its object. Indeed, the burdensome nature of the restrictions led in many instances to their evasion and consequent failure to protect the community. Unfortunately there were many such failures in the operation of every quarantine; and the opposition did not hesitate to affirm that the quarantine system was a barbarous imposition of the middle ages, of no value as a protective measure, and operating merely as an impediment to commerce. The reply to this acknowledged the inability of quarantine to guarantee protection, but claimed that the chances of importation were reduced in proportion to the care with which the regulations were enforced. "Shall we," as Sir Sherston Baker says, "abolish the fire brigade because a row of houses are burned down? Shall we dismiss the police force because a dozen burglaries have occurred? Shall we denounce the system of railway signalling because a false signal has caused a fatal catastrophe?"

The immense importance of her commercial relations to England has made that country a leader in the establishment of a sanitary system which will give adequate protection without imposing the burdensome restraints of former times. Originally her quarantines, directed against the plague, were formulated on those in existence at the Mediterranean seaports; but since cholera became the pestilence specially to be guarded against, a system of sanitary inspection has been urged for adoption at the Red Sea stations, and accepted as the only needful measure at her home ports.

Quarantine regulations did not take practical shape in Britain until the beginning of the present century. Consular officers at foreign ports furnished bills of health to vessels clearing for the United Kingdom. A *clean* bill implied that no infectious disease existed at the port of departure at the time of sailing, nor had existed for forty days prior to that time. This did not entitle the vessel carrying it to free pratique unless the superintendent of quarantine was satisfied that her crew and cargo were free from suspicion; and, indeed, all vessels laden with cotton from Alexandria were obliged to undergo quarantine irrespective of the character of their bills of health. A *suspected* bill was given to vessels when the port of departure, although free from disease, had commercial relations with infected ports or places. A *foul* bill was issued when the port of departure was itself infected. All vessels coming from a port which had been officially declared dangerous in view of the existence of plague or other infectious disease or distemper, and all vessels, boats, persons, or goods that had been in communication or contact with any vessel so coming or having touched at an infected port, were declared liable to quarantine. Against yellow fever from America or the West Indies an inspection station was provided, that the health of the crews of incoming vessels might be ascertained, but such vessels were not subjected to quarantine unless specially ordered. The Privy Council was authorized to make such orders,

upon emergencies, as it might consider necessary. Masters of vessels from foreign ports were required to give to pilots an accurate account of all the places at which they had touched on the homeward voyage; and it was incumbent on the latter to give information of any change in the regulations, involving the liability of a vessel to quarantine restrictions, that masters might be assumed to be ignorant of by reason of their recent voyage. At the port of destination, in suspicious cases, a quarantine inspector interrogated the incoming vessel from a proper distance, to ascertain the sanitary condition of the port or ports at which she had touched on her homeward voyage, and the history and character of any sickness that may have affected the crew or passengers; if he found her liable to quarantine, she was obliged to proceed to the station, as the naval, military, and civil powers of the government were subject to calls for the enforcement of the laws. When the vessel reached the quarantine station a full record of her sanitary condition and history was made, and if she was reported by the superintendent as fit for entry into her port of destination without further detention, the Privy Council was authorized to direct her immediate release. Vessels with clean bills of health from the Mediterranean and West Barbary on the Atlantic Ocean were required to undergo a limited quarantine, for the purpose of breaking open the cargo and airing it prior to delivery; and certain places were appointed as quarantine stations for this purpose, such as Standgate Creek for vessels bound for the ports of London, Rochester, and Faversham; Milford Haven for Carlisle, Liverpool, etc.; Inverkeithing Bay for the eastern ports of Scotland; and so for other sections of the coast. These vessels were detained fifteen days from the date of their arrival, during which time all goods were aired on deck; but if the cargo of the vessel consisted in whole or in part of certain classes of goods conceived to be of a retentive or dangerous character, these were required to be removed for aëration to a special quarantine float, and the detention of fifteen days dated from the time of the discharge of the cargo. The list of dangerous articles was long, and included all cotton, silk, and woollen goods, furs, straw, etc. Vessels with suspicious bills were detained at the station for thirty days, during which they were daily subject to inspection; and if at any period of their stay a pestilential disease was discovered among the crew or passengers, the quarantine period was recommenced and the vessel treated as newly arrived and plague-stricken. Vessels liable to quarantine were required to indicate their condition when passing other vessels or approaching the coast by flying a yellow flag or showing a light at the mainmast-head. Merchant-vessels with foul bills, but not having the plague on board, were restricted in their choice of quarantine stations to Standgate Creek and Milford Haven, where there were better facilities for caring for the sick and handling suspected cargoes. War-ships under similar circumstances repaired to a special station at Motherbank, where a floating lazaret was established for their benefit. If plague appeared on a vessel while *en route*, she was required, if to the southward of Cape St. Vincent, to proceed to some lazaretto in the Mediterranean, there to undergo quarantine; and on her arrival on the coast of the United Kingdom she reported to the superintendent of the station most convenient for her, and awaited the special orders of the Privy Council in her case. All other plague-stricken merchant-vessels repaired to the quarantine grounds marked out at Milford Haven by twelve yellow buoys. Here guardians were appointed to see that these ships were thoroughly searched and cleaned after the removal of their cargoes. No communication was held with them except by letters which had been dipped in vinegar and fumigated; and nothing was delivered without the quarantine lines from on board except on the order of the superintendent. The sick were transferred to a floating hospital; separate accommodations were provided for the healthy and for convalescents and invalids during the period of their detention; the cargoes were unloaded for aëration and disinfection, and the vessels subjected to thorough cleansing and fumigation. In case of death at quarantine the body was required to be sewed up in canvas, weighted with one and one-half hundredweight of iron, and committed to the deep, the infected clothes and bedding being destroyed. The government provided medical attendance, medicines, disinfectants, and the use of the quarantine floats, shelters, furniture, and appliances, free of expense to the detained vessels, and no quarantine fees were charged.

In 1871 the powers and duties relating to quarantine and public health vested in the Privy Council were, as regards England and Wales, transferred to the Local Government Board. Two years later, when cholera was prevalent in certain parts of Continental Europe, the Board issued orders with a view to the better protection of the country from epidemic invasion. The officer of customs was required to detain any suspected vessel for inspection, immediately notifying the port or local sanitary authority; but if no action was taken thereon within twelve hours, he was authorized to release the vessel. The local sanitary authority was required to cause the immediate inspection of any suspected vessel, whether detained by the officer of customs or not, to ascertain whether she was infected. Healthy persons were permitted to land without delay; those affected with diarrhœa or other suspicious sickness were detained on board or in some previously appointed place for a period not exceeding two days, for the determination of the character of their illness; those certified as affected with cholera, and those suspects who developed disease during their temporary detention, were removed to some appointed place, or, if unfit for removal, were retained on the vessel, which they were not permitted to leave save on the authority of the proper officer. The vessel and her contents were required to be disinfected, dangerous articles, such as the clothing and bedding of those who had suffered, being destroyed if considered necessary.

The local authorities of English ports, under the supervision of the Local Government Board, make provision, at the present time, for the relief of vessels suffering from other dangerous infectious diseases, as diphtheria, erysipelas, measles, small-pox, scarlet, enteric, typhus, and relapsing fevers; and for this purpose floating hospitals are sometimes used. That launched at Newcastle-on-Tyne in August, 1886, may be instanced as one of the best construction, not only as being the latest, but as the product of a port noted for its ship-building industry (see Fig. 3225). It is built on ten cylindrical iron pontoons resembling huge boilers, each 70 feet long, 6 feet in diameter, and having a buoyancy of $53\frac{1}{2}$ tons, so that the floating power of the hospital is equal to 535 tons. On each pontoon are seven saddles, which support a strong framework of longitudinal rolled-iron girders braced together by diagonal T-iron. This supports a deck of creasoted timber, which constitutes a platform on which the hospital is erected. It is surrounded by a neat handrail, and access from the river is obtained by a gangway in the front centre of the protection-rail. The deck is partly occupied by three main buildings, six smaller structures, and a mortuary. Each of the main buildings, $65 \times 23\frac{1}{2} \times 20$ feet, is divided into two wards, one containing six, the other four, beds. The interiors are spacious, lined with polished pitch-pine in narrow strips, well lighted and ventilated by inlet apertures near the floor and a shaft through the roof fitted with Kiles' patent ventilator. Between the two wards of each building is an apartment for the nurse, fitted on either side with glazed doors to afford full view of each ward. The three buildings are all fitted up alike, and are so arranged that each can be completely isolated. As the platform is 140 feet long by 80 wide, there is ample space in front of the buildings for the recreation of convalescents. Beneath the floor is a clear space of ten inches, to secure free access of air between it and the deck; and between the platform and the water-level is a space of four feet. The rise and fall of the tide and the current in the spaces between the pontoons prevent the possibility of any impurity beneath the hospital. The space between adjoining pontoons is $14\frac{1}{2}$ feet from centre to centre, and each is detachable for cleaning, painting,

or repairs; they may also be revolved in their places without removal.

The gradual progress of the emancipation of commerce from the onerous impositions of earlier times, and the better protection of Europe from plague and cholera by measures based on the scientific study of disease, may be best appreciated by following the history of the international conferences that have been held from time to time.

In July, 1851, an international conference on the subject of quarantine was held at Paris, delegates from most of the European states being present; the results of its deliberations were subsequently ratified by France, Sardinia, Portugal, Tuscany, and Turkey. Only foul and clean bills of health were recognized by the convention, the first for the assured presence of the malady, the second for its attested absence; and for the more easy application of quarantine measures a maximum as well as a minimum of detention was agreed upon. For the plague, ten to fifteen days; for yellow fever, three to seven days for vessels without casualty during their voyage, and seven to fifteen days for those having had sickness *en route;* for cholera, three to five days, including the duration of the voyage, but if cases occurred *en route* the time occupied by the voyage was not taken into account. Merchandise was divided into three classes: 1, Articles subject to an obligatory quarantine and purification—these included old clothes and articles of common use, rags and waste-paper, leather and skins, feathers, hair, and, in general, any parts of animals, and, lastly, wool and silk stuffs; 2, those liable to quarantine, including cotton, flax, and hemp; and 3, those exempt from all restrictions, comprising all articles not belonging to the first or second class. Each of the contracting parties agreed to furnish and maintain the lazarets required by the exigencies of the public health, the convenience of travellers, and the requirements of commerce; and in order not to impose on the shipping of their respective states more than the charges needful to cover the expenses of maintenance, certain dues and taxes were indicated. Sanitary councils were established in the principal ports and cities, and the consuls of states accepting the terms of the convention were entitled to be present at the deliberations of these councils and to be heard when the interests of their country were involved. The regulations provided for the thorough cleaning of all merchant-vessels at the port of departure before taking in their cargo, and for the medical examination of the crew and passengers. Certain measures of cleanliness and ventilation were required to be carried into effect during the voyage. On arrival at the port of destination the vessel was inspected and admitted to free pratique or detained to effect the requisite cleanliness, for a quarantine of observation, or for the performance of a strict quarantine, as seemed necessary from her history and condition. Strict quarantine involved purification and disinfection. The occurrence of yellow fever, cholera, or plague during the period of detention necessitated a renewal of strict quarantine. Regulations were formulated for the arrangement, supervision, and interior management of lazarets, including the disposition of cargoes, wearing-apparel, and mails. Provision was also made for the sanitary supervision of Turkey and Egypt. The Superior Council of Health at Constantinople, which was to superintend this service, had added to its membership a number of delegates from the states signatory to the convention equal to that of the Ottoman functionaries and having equal voice with them in the deliberations. At Alexandria a similar board of health was constituted. Medical inspectors, appointed by the powers interested, were distributed over the East to study, in relation to the public health, the country in which they were stationed, its climate, diseases, and characteristics, and the means adopted to combat the disease; and to this end they were required to make tours of inspection through their respective districts as often as deemed desirable. In case of an epidemic or suspicious outbreak these inspectors were required to report immediately to superior authority. These regulations were in force for five years, but were not renewed at the end of that period.

The Conference of Constantinople, in 1866, enunciated certain guiding principles of practical action. It recognized the origination of cholera under certain unknown conditions and its endemic existence in India, particularly in the valley of the Ganges; the possibility of its naturalization on European soil was considered problematic. Its propagation was effected, not by atmospheric conditions, but by the agency of man, and with a rapidity proportioned to the speed of his methods of travel. The cholera patient, or person suffering from premonitory diarrhœa, was the chief agent in its spread, the choleraic discharges being regarded as the dangerous element. The period of incubation did not exceed a few days. It was considered reasonable to suppose that living animals were capable, in certain cases, of transporting the disease. Articles in common use by choleraic patients and their attendants were efficient transmitters—even from afar, if protected during transportation from the action of the air. The possibility of its transmission by merchandise was admitted, in the absence of proof, and it was pronounced safest to consider as infected and dangerous all productions of an infected locality. Moreover, although there was no positive evidence of danger from the bodies of choleraic dead, it was considered prudent to regard and treat them as infected. Sea and railroad travel were announced as the most dangerous methods of communication, while deserts traversed only by caravans were regarded as an effectual barrier to the transmission of the disease. All

aggregations of men, pilgrimages, fairs, armies, etc., favored the extension of cholera, while its violence was proportioned to the absence of immunity on the part of individuals and to general insanitary conditions, as poverty, overcrowding, deficient ventilation, and impurity of soil, particularly if the impurity is in part derived from choleraic dejections. On shipboard, intensity is proportioned to overcrowding with susceptible material; but the danger of importation has no relation to this intensity. So, in a lazaret, the aggregation of persons coming from a place where cholera prevails does not produce a great increase of the disease among them, owing to their relative immunity; but such a lazaret is dangerous to its susceptible neighborhood.

As relating to prevention: The conference appreciated the efforts of Britain to restrain and extinguish the disease in India by general and special sanitary measures, but concluded that as these could not be efficient at an early date, it was meanwhile needful to guard against importation. For this purpose a system of maritime sanitation was suggested, and it was advised that there should be: Competitions and prizes for discoveries or improvements the immediate results of which would promote the sanitary condition of vessels, the health of their crews, and the well-being of their passengers; a manual of hygiene for the use of the merchant-marine of every country, the most important rules of which should be obligatory; and encouragement by premiums and rewards to those who should distinguish themselves by the excellent management of their vessels and crews. The sanitary conservation of ports was considered as of great importance; this included the exclusion of city sewage from the waters of the harborage and measures of general cleanliness, having reference to purity of air, water, and soil, particularly the protection of the last from choleraic infection. It was held that restrictive measures, properly applied, did less harm to commerce and international relations than the disturbances consequent on epidemic visitation, and that quarantines, based on rational and scientific views concerning the transmissibility of cholera and its mode of propagation, were an efficient barrier against its importation. As the disease came from India by way of the Red Sea, overland through Persia, or from secondary foci in Arabia, all these modes of progress were reviewed, and appropriate recommendations given. The establishment of a quarantine station in the Red Sea, under international control, was advised, with special stations for vessels carrying pilgrims. A sanitary service for the protection of the overland route was suggested, with a quarantine of ten days when the arrivals had not been more than three days on the journey; the immediate sequestration of first cases was approved, together with the early isolation of an infected locality and the use of sanitary cordons, which, although of uncertain value and often dangerous in wide-spread epidemics and dense populations, were regarded as affording good results in limited localities or sparsely settled countries, as in some parts of Asia. A special sanitary service was also recommended for the Hedjaz and its pilgrimages, involving non-intercourse between Arabian and Egyptian ports during the progress, and for fifteen days after the cessation, of any cholera epidemic among the aggregations of pilgrims. Islands otherwise unoccupied, or isolated localities distant from centres of population, with good air and water, a rocky and non-malarious soil and ample harborage, were recommended as quarantine sites. Floating lazarets were not considered satisfactory. Quarantine quarters were to consist of one-story cottages, each of four rooms, with accommodation for five persons in a room; the distance between adjacent houses to be twenty metres, and that between adjacent rows one hundred metres. The hospital, including officers' quarters, dispensary, wards, kitchen, laundry, and store-rooms, to be at least two hundred metres distant from the quarters, and to be formed of a similar series of detached cottage-buildings, each ward to contain from five to ten beds. Two landings to be provided, one for persons and goods subject to quarantine, and the other for unrestrained commerce; warehouses to be near the landings, with special accommodation for goods requiring purification, and stables and sheds for animals. Movable vessels, charged with disinfectants, to be used in the privies of all sections of the establishment, their contents thereafter to be buried under quick-lime and animal-charcoal. Quarters of the quarantine guard to be at least two hundred metres from other buildings. It was considered advisable that stations thus equipped to carry out the measures of a strict quarantine in the case of infected vessels should be as few in number as was consistent with the requirements of the traffic and coast-line of a state. Quarantines of observation, which involved watching merely, might be performed without inconvenience or danger at less elaborate stations, or even on shipboard in the vicinity of large ports. The quarantine period was fixed at ten days; but vessels in which all sanitary precautions had been taken, including inspection at the port of departure, and which carried a commissioned medical officer, had the time spent on the voyage included as part of the quarantine period. Vessels on which no suspicious disease was developed during the voyage were merely detained, or subjected only to such general hygienic measures as seemed desirable, and if the voyage had lasted fifteen or more days the quarantine was reduced to five days. Those which were infected had to discharge cargo and submit to special means of purification, as by fumigation with chlorine. Those in which a severe epidemic had occurred were to be treated with the utmost precaution, even to prolonging or doubling the ordinary period of detention.

The Conference of Vienna, in 1874, adopted the conclusions reached at Constantinople concerning the origin and transmission of cholera. Land quarantines were rejected as inefficient and impracticable, in view of the increasing facilities for communication and the injury they inflict on commercial interests. The substitution of a system of medical inspection for quarantine at European ports, with the establishment of a rigorous and truly preservative quarantine during the passage of the Red Sea, was strongly urged by Semmola, of Italy, in submitting to the conference the report of a sub-committee on seaport quarantines. The Red Sea was considered the strategic point in the line of defence against cholera invasion. Hirsch, of Germany, and D'Alber-Glanstätten, of Austria, also spoke in favor of these views, which were vigorously attacked by Sousa-Martins, of Portugal, who was inclined to hold that, outside of quarantine, science recognized no sure means of preventing the importation of cholera; that the failure of quarantine measures was caused by the neglect or infringement of the laws governing the propagation of the disease, and that commerce suffers more from epidemics than from quarantines. The committee, he argued, must be of the opinion that quarantines were based on scientific views, since they had been accepted by its members, who were scientific men; that they were practicable, else they would not have been recommended as the only defence of Europe against invasion, and that at Suez and Alexandria, at least, they were less to be feared in their economic consequences than the evils consequent on the diffusion of epidemic cholera. But why confine the application of these accepted principles to the towns mentioned? Was quarantine more efficacious there than elsewhere? Was there more likelihood of arresting the progress of an epidemic at its points of irruption than at places where its progress was less rapid? Would cholera be less fulminant at Suez, where pilgrims arrived by the thousand, than at Marseilles, Gibraltar, or Lisbon? Have the ports of Europe fewer facilities for carrying out quarantine measures than those of Egypt, or do Alexandria and Suez present topographical conditions which do not exist in Europe? He charged the committee with conceding that, in the event of the introduction of the disease, its epidemic diffusion was certain notwithstanding all quarantine measures. Was amputation of no avail when gangrene supervened? Yet it was acknowledged, by the recommendation for a Red Sea quarantine, that the only protection available for

Europe lay in these same quarantine measures. There was inconsistency in this. The report of the committee was defended by several of its members, the principal argument being that when cholera passed the Red Sea and appeared in Europe, European quarantines could do no more than attempt the isolation by sea of countries that were in daily communication by land. M. Fauvel, in objecting to the withdrawal of European quarantines, argued that in some countries sanitary interests, in others commercial interests, were prominent, and that the utility of quarantine was regarded differently according as one or the other of these interests predominated. The northern countries of Europe, besides having been less devastated by choleraic epidemics, had more exacting commercial interests than the southern countries, and were therefore inclined to view quarantines only as impositions or restrictions on their commercial relations. Even the same government did not always view the question of quarantine from the same stand-point. England, although desiring no quarantine at her home ports because commercial interests were superior to all others, did not hesitate to impose the most rigorous measures where these interests demanded the protection of a port from infection. At Malta the strictest quarantine of the Mediterranean was in force, and at Gibraltar suspected vessels had been refused admittance. In France the channel ports coincided in the views of the northern countries, the Mediterranean ports with those of the south. All are actuated by the dominant interest. To say that seaport quarantines are useless because cholera may come by land is an argument invoked only in behalf of interests that have not the public health for their objective. We know that quarantines prevent importation. They do not guarantee safety; but why should that perfection be required of quarantine that is not required of any other human institution? It is true, also, that seaport quarantines lose much of their value when directed against an epidemic in their immediate neighborhood. But we must be content with the best possible protection. If the means of prevention employed increase in some degree the chances of preservation, and do not involve sacrifices greater than the guarantee of protection afforded, they should be considered advisable and worthy of adoption. As a result of these discussions, the conference approved the recommendations of the Conference of Constantinople concerning the establishment of a strict quarantine in the Red and Caspian Seas to prevent the introduction of cholera into Europe. In the event of invasion a system of medical inspection was recommended, but for those states which preferred to continue quarantine restrictions certain regulations were adopted.

The *inspection system* provided that every commercial port should have a sanitary service competent to deal promptly with all vessels, crews, and passengers. Vessels from a healthy port, not having touched at an intermediate suspected port or communicated directly with a suspected vessel, and having had no sickness of a suspicious nature during the voyage, were admitted to free pratique. Arrivals from a suspected or infected port, or those having had compromising relations or suspicious sickness during the voyage, were to be submitted to a rigorous medical inspection, when, if no infection was discovered, the vessel and all on board were granted immediate admission; but if it was found that cholera or sickness of a suspicious nature had existed on board before arrival, the vessel and the clothing and other articles in common use by the crew and passengers were to be carefully disinfected. If the incoming vessel contained persons sick or dead from cholera, the sick were removed to a lazaret or other proper place and the dead committed to the deep or buried after suitable disinfection, and the crew and passengers, their effects, and the vessel itself thoroughly disinfected, but the cargo, save when consisting of rags or other susceptible articles, was admitted without treatment.

The *quarantine regulations* for arrivals from infected ports provided for a period of observation ranging from one to seven days when no disease was present on arrival; but at the eastern ports of Europe, and elsewhere in exceptional cases, this period was extended to ten days. If proof was found that no suspicious case had occurred during the voyage, three to seven days' detention was required; but if the voyage had lasted at least seven days, the period of observation was reduced to twenty-four hours; and these quarantines might be performed on board the vessel, provided she was in suitable sanitary condition. When cholera had occurred during the voyage or after arrival, persons not sick, except such as were required for the care of the vessel, were isolated in a lazaret or other suitable place; the sick were landed and cared for separately, and the vessel and all susceptible articles were disinfected, after which those persons who remained on board were kept under observation for seven days. For arrivals from suspected ports, and in the absence of any suspicious accident during the voyage, the period of observation was limited to five days. Emigrant and pilgrim ships and others deemed particularly dangerous to the public health became the object of special precautions, to be determined by the port sanitary authority. When the port of arrival was unprovided with proper quarantine facilities, an infected ship was to be directed to the nearest lazaret after receiving such succor as her condition required. A vessel coming from an infected port, but having touched at an intermediate port, where she had received free pratique without having undergone quarantine, was to be treated as coming directly from an infected port. In cases of mere suspicion, disinfection might be resorted to when considered expedient by the sanitary authority, but it was not to be regarded as obligatory. A port in which cholera prevails epidemically should cease to quarantine, and practise only measures of disinfection. For inland river towns the system of medical inspection was recommended as applicable. It was decided, as pertinent to both the inspection and the quarantine system, that the captain, medical officers, and other officers of a ship are bound to furnish to the sanitary authority every information concerning the occurrence of suspicious disease among the crew or passengers, and in case of false representations or wilful concealment they are liable to penalty under the sanitary laws, on which subject it was considered desirable that there should be an international agreement. The details of disinfection were left to the sanitary authorities of each country. The conference also recommended the institution at Vienna of a permanent International Sanitary Commission, having for its object the study of cholera and other epidemic maladies from the stand-points of etiology and prophylaxis, and the coordination of researches into these subjects undertaken by the various contracting states.

The English delegates at this conference urged the adoption of the system of medical inspection instead of arbitrary quarantine rules, and presented a communication from the Medical Officer of the Privy Council giving the views of the Local Government Board on the propagation of cholera in England. These held importation of the infection to be of secondary importance; local filth and unsanitary conditions which afforded the imported infection a soil favorable for its development were regarded as the principal agencies. The precautions to be taken embraced the removal of the filth, the protection of water-supplies, and, in the event of invasion, the disinfection of choleraic discharges, in which the infective power is known to reside. But the main object of England at this conference was evidently to secure such action as would permit her vessels from India to traverse the Red Sea without embargo by either quarantine laws or international inspections. Something was accomplished in this direction before the Superior Council of Health at Constantinople in 1882. The delegate from England, in presenting a communication from the Governor-General of India opposing quarantine restrictions on English vessels from India, represented that the fears of an importation of cholera were based upon the theoretical views of the Conferences of Constantinople and Vienna, and not upon facts. Aden, he instanced, is in daily communication with Bombay and other Indian ports, which are distant but a few days' journey, yet it

has not suffered from the disease during the years 1868–80, and its history, so far as known anterior to 1865, confirms the experience acquired since that time. After full discussion the council adopted certain propositions recognizing the great danger of the introduction of cholera by the often foul and always crowded ships carrying pilgrims to Mecca, and authorizing the free admission of vessels in good sanitary condition, having no pilgrims on board and no suspicion of cholera during the voyage, inasmuch as no instance has been recorded of the introduction of the disease by vessels not carrying pilgrims, and permitting arrivals under these conditions from ports that are known to be infected to have the duration of the voyage considered as part of their quarantine term, which shall be completed by twenty-four hours of observation.

Meanwhile an International Conference was held on this side of the Atlantic. It was called by the President of the United States, in compliance with a joint congressional resolution, for the purpose of securing an international system of notification as to the actual condition of ports and places likely to be infected with cholera or yellow fever, and the establishment of a uniform and trustworthy system of bills of health. The exposure of this country to yellow fever, and the difficulty experienced by our consuls at foreign ports in obtaining the co-operation of the local authorities in their efforts to verify and improve the sanitary condition of vessels clearing for United States ports, were the chief agencies in the inception of this conference. It was held in Washington in the early part of 1881, and thirty-one governments were represented at its sessions. The resolutions adopted looked to: 1. The establishment by each government of such an organized internal service as would enable it to be regularly informed of the state of the public health throughout the whole of its territory. 2. The publication, weekly, of the mortality statistics of its principal cities and ports. 3. Direct communication between the sanitary authorities of the countries concerned. 4. The creation of international organizations for the collection of information regarding the outbreak, spread, and disappearance of cholera, pest, yellow fever, etc., and conveying such information to the parties interested. 5. The acceptance by the authorities of the various countries of a bill of health after the form approved by the conference. 6. The delivery of the bill at the port of departure by the territorial sanitary authorities, and the right of the consul of the country of destination to be present at the examination of ships, to authenticate the bill, and to make thereon such remarks as he might deem necessary. 7. Gratuitous issue of the bill. 8. The creation of a temporary scientific sanitary commission by the nations most directly interested in protecting themselves against yellow fever, and of such others as might wish to take part in this arrangement, for the purpose of studying all matters pertaining to the origin, development, and propagation of that disease.

Had this conference restricted its efforts to the ends for which it was specially called, it is probable that a convention might have subsequently ratified its conclusions, and international communication relative to epidemic diseases, with uniform rules pertaining to the issuance of bills of health, might have been obtained as a protection to both the public health and the interests of commerce; but, unfortunately, some enthusiastic sanitarians urged the adoption of the eighth resolution, which, by calling for the establishment of twenty-two international posts for the study of yellow fever, each provided with chemical and histological laboratories, libraries, and expert physicians for their use, with provision for an annual conference, at which at least one member from each post should be present, implied a financial expenditure for its support sufficient to prevent any practical action from being taken on the conclusions of the conference, if it did not throw doubt upon the whole of these conclusions as being apparently the work of medical visionaries. As it was, no action was taken by the Government to realize any benefit from the deliberations of the conference.

The last conference was convoked at Rome, in May, 1885, by the Italian Government, with the view of settling the basis of an international agreement as to measures of prevention that would be acceptable to all the governments, and of forming rules for the application of such an international system of sanitary intelligence as had been proposed at Washington in 1881. The following summarizes the conclusions of a technical commission consisting of the medical delegates, to which the duty of preparing suitable resolutions was referred: It was considered necessary that there should be in every country a central bureau for the interchange of information concerning sanitary conditions, for the publication of an international bulletin giving weekly bills of mortality from all important cities, and for the transmission of telegraphic notice to all concerned of the extension of cholera or yellow fever to new localities. Under the heading of Sanitary Prophylaxis in Cholera, it was considered that purification and isolation, in the measure indicated by science, of everything that may carry the infection of cholera were the best means of preventing the importation and propagation of that disease. As disinfectants, steam, carbolic acid, and chloride of lime were recommended; for certain articles, boiling in water for thirty minutes, and when these measures are impracticable, destruction or an aëration by exposure for three or four weeks. Disinfection of merchandise and mail-bags was not considered needful; but superheated steam was suggested, parenthetically, as the only available means if the disinfection of rags in bale was desired. Land quarantines and sanitary cordons were affirmed to be useless; the propagation of cholera by land was to be combated by general sanitary measures, taken in advance, and the prompt isolation of newly developed cases, with effective disinfection under the supervision of an organized sanitary service. Travel by rail from infected places was to be effected under medical guardianship, which had at each station means of isolation for cases developed *en route*. In passing into an uninfected district, passengers and freight were to be transferred to other cars, that those from the infected territory might be retained within it. Disinfection of passengers and merchandise was declared to be necessary only when there had been contact with choleraic dejections. River-ports open to sea-going vessels were considered seaports so far as concerned protective measures; but interior river navigation required rigorous medical inspection, stations being provided for the treatment of infected vessels.

The importance of general sanitary measures at seaports was urged. These should be effected under the supervision of a special sanitary authority. The consul at the port of departure should have the right of assisting at sanitary inspections of vessels made by the territorial authority, in conformity with the rules established by convention or treaty. The lading of the vessel at the infected port should be begun only after thorough cleaning by ordinary means or specially by disinfection, as might be required. The crew and passengers should be examined, and those suspected of choleraic disease should not be permitted to embark, nor should any suspected bed- or body-linen or other articles be admitted on board. These measures devolve on the captain and medical officer of the vessel prior to inspection by the territorial authority; but if the vessel does not carry a medical officer, the consul of the port of destination should appoint a suitable person to perform these duties.

Recommendations were made for the management of the vessel during the voyage, and particularly in case of the development of choleraic disease. All steamers passing through the Red Sea from infected Indian ports should be subjected to inspection by an independent, *i.e.*, an international official, and if the medical officer of the vessel certifies that all necessary precautions have been taken at the port of departure and during the voyage, and that there is no one on board affected with cholera or any sickness of a suspicious character, free pratique should be accorded by the inspecting officer. Vessels with passengers for the ports of Egypt or the Red Sea

should be inspected near the Straits of Bab-el-Mandeb, and again on arrival at the port of destination; but those passing through the sea merely *en voyage* require inspection at Suez only. If at the inspection the vessel is found to be infected, the passengers should be landed, the sick isolated and properly cared for, and the others subjected to observation for five days, while the ship, clothing, bed-linen, and other suspected personal effects are disinfected. Vessels not carrying a medical officer should be subjected to two inspections, one within the straits and the other at Suez, although they may be merely *en route* to the Mediterranean and have no commerce with the Egyptian or Red Sea ports. Special provisions of a more rigorous nature were adopted for the treatment of ships carrying pilgrims from India to the Hedjaz, and for those returning from the pilgrimage to Egyptian or Mediterranean ports.

On arrival at European ports suspected vessels were to be considered entitled to free pratique only when inspection in the daytime by the medical officer of the port revealed that all needful precautions had been taken before sailing and on the voyage, that no case of a suspicious character had occurred on board, and that ten days at least had been spent *en route*. If this period had not elapsed since leaving port, a detention of twenty-four hours was required for observation, with disinfection of soiled linen and other suspected personal effects. In the case of infected vessels, the port sanitary authority should cause the landing of the crew and passengers, the sick to be isolated and cared for, the well to be under observation, and the vessel, personal effects, and other dangerous articles to be disinfected. The period of observation was limited to five days; but if no case of cholera had occurred on board for ten days, the detention was reduced to twenty-four hours, as in the case of vessels merely suspected. Suspected vessels from Mediterranean ports were required to disembark their crew and passengers at a suitable place for observation, the period to be limited to from three to six days including the time spent on the voyage. Infected vessels were to be treated as in the case of those bringing the disease from India or the Red Sea.

The summary of the conclusions of the technical commission of this conference does not contain the word "quarantine" in connection with preventive measures to be taken at seaports, but it does not follow that the abolition of quarantine was recommended in favor of a system of medical inspection. On the contrary, the commission, while disusing the word, insisted on the measure with more force than did the Vienna Conference. The latter left the option of quarantine or sanitary inspection to the countries concerned, but the former imposed a detention of twenty-four hours in cases where the sea-voyage from suspected ports beyond the Mediterranean had lasted less than ten days, and a quarantine of from three to six days on suspected vessels from Mediterranean ports, with no proposition looking to the system of medical inspection as an alternative.

Having thus reviewed the efforts made by Europe to supersede arbitrary time-quarantines by protective measures based upon a knowledge of the natural history of epidemic diseases, we may turn to this country to learn in what manner medical progress has affected the local quarantines established in colonial days. It will be seen that here, as in Europe, the tendency of the time is to secure the greatest possible protection to the public health with the least possible injury to commercial interests, to abolish quarantine detention, substituting for it a system of medical supervision which will obviate the necessity for detention except in the case of manifestly infected vessels.

Quarantine powers have always been regarded as belonging to the States, and although several efforts have been made to secure the enactment of a general quarantine law, these have failed, apparently from the disinclination of the States to cede their powers in this respect to the General Government. The wide-spread devastation caused by yellow fever led, in 1796, to the discussion of a national bill for the regulation of quarantine. This authorized the President to institute quarantine at ports of entry, and to specify its duration. Its second section directed the use of the revenue service in carrying out the quarantine law and the health laws of the States. The power of dictating and regulating quarantine, to be vested in the President, was voted down by the House of Representatives, but the second section was passed. To this the Senate attached an amendment, implying the bill to be merely a temporary aid to existing protective measures, which should remain in force only until general regulations relative to quarantine were made by law. But this assertion of the power of the National Government to regulate quarantine was objected to in the House of Representatives, and the second section of the original bill was passed without amendment. This was followed and repealed, in February, 1799, by an act in which the possession and exercise of quarantine powers by the States was fully and distinctly recognized, certain Federal officers, such as all officers of the customs, masters of revenue-cutters, and military officers commanding posts or stations on the seacoast, being required to aid in the execution of the quarantine and health laws of the States, according to their respective powers and within their respective precincts, and subject to the direction of the Secretary of the Treasury.

For nearly three-quarters of a century no further effort was made to protect the country by national legislation. Meanwhile its quarantine laws became a heterogeneous conglomeration of impositions on commerce, without affording commensurate protection. Some small ports on the Gulf and Southern parts of the Atlantic seaboard, which, from their relations with the West Indies, had more or less familiarity with yellow fever, imposed no restrictions on their commerce, and the interior became exposed to epidemic invasion through these otherwise unimportant places. Other ports had only a nominal quarantine, because the revenue from fees was insufficient to defray the expenses of its management. Generally, however, there was some kind of quarantine regulations, but in few instances, save at certain large commercial centres, were they efficiently carried out. The value of quarantine became assailed on account of the inefficiency of its administration, and the opposition was for a long time strengthened by conflicting views concerning the origin of yellow fever. During the epidemic in Philadelphia, in 1793, the doctrine of its indigenous origin was advanced for the first time, and since then this has repeatedly been brought forward as an argument against quarantine restrictions. The extended experience of recent years has, however, apparently settled this question. Most of the epidemics have been traced to imported infection, although in a few instances, as at Newbern, in 1864, and Savannah, in 1876, the indigenous origin of the fever has been strongly urged. Moreover, the meteorological and local hygienic conditions of Southern cities during periods of freedom from disease have not differed essentially from those presented by epidemic periods. There are, therefore, few sanitary officers to-day who do not regard this fever as an exotic which may be excluded by suitable quarantine measures, but which, in the event of its introduction, may, under favorable protective conditions, survive the winter on the Gulf coast and reappear during the following summer without a fresh importation.

But although defective in their administration, so far as concerned protection, the seaport quarantines seldom failed to gather a tax from incoming vessels under the form of quarantine dues. Indeed, in some instances quarantine resolved itself into the collection of this tax in return for the official papers necessary to free pratique. According to Dr. Brown, "There is a great deal in the various laws about inspections of log-books, manifests, and bills of health; mustering of passengers and crew; examination of masters and others under oath; but practically all these requirements are seldom enforced. What actually takes place is for the health-officer to come on board as soon as the vessel heaves to off the quarantine ground, hurry to the captain's or purser's office, and, if she come from a non-infected port, simply inquire if all

are well on board, receive his fee, and depart as soon as possible. If from an infected port, he directs the master to bring his ship to anchor, and does not concern himself further about her unless she have sickness on board. During his brief stay on board, the steward of the ship is generally engaged in loading the health-officer's boat with fruit, ice, or other delicacies, which are received as a matter of course; and, indeed, any omission in this particular has been known to subject certain lines to great inconvenience. Lest this may be thought an exaggeration, I may mention that the health-officer of one of the Southern ports told me, some years ago, that he saved all his salary, as he was entirely supported by the great variety of articles he received in this way. As at present administered, the visits of inspection are simply a farce, the only object being to collect the fee and receive the *douceurs* which are the perquisites of the health-officer."

Quarantine fees at some of the Southern ports, particularly those of Texas, yielded a considerable revenue, and were a corresponding burden to the commercial interests. The States, according to Justice Bradley, "have a right to establish quarantine regulations for the protection of the public health, but they have no right to place toll-gatherers at the gateways of commerce and lay indiscriminate exactions upon all vessels that enter thereby." Even at the port of New York quarantine dues by far exceeded the necessities of the occasion, whereby the service and its officers became repeatedly subjected to adverse criticism.

In 1872, Dr. Harvey E. Brown, U.S.A., made a thorough inspection of the quarantines of the Southern ports exposed to invasion by yellow fever, in accordance with a joint resolution of Congress, providing for a more effective system of quarantine on the Southern and Gulf coasts. In his report this officer stated that these quarantines, being established by State or municipal authority, lacked that uniformity which is absolutely necessary to their efficiency, were not founded on rational views of the pathology of the disease, and were generally defective in their administration. To remedy the evil he recommended the assumption of quarantine by the General Government, and its administration by the War Department; claiming that only in this department of the Government is found that freedom from political influences and that authoritative management which demands absolute obedience to law, while granting the largest liberty to the individual consistent with the public safety. The Surgeon-General, in forwarding this report, did not endorse its recommendation for the transfer of quarantine duties to the medical corps of the army, as he conceived that the imposition of these responsibilities would materially interfere with the interests of the military service.

As the result of this investigation, a bill for a national quarantine passed the House of Representatives at its next session, but failed in the Senate. This bill proposed the institution of a quarantine board consisting of the Surgeon-Generals of the Army, Navy, and Marine Hospital Service, to formulate regulations which should not conflict with existing State regulations—these to be enforced by a quarantine officer specially detailed from one of the services. Its failure was ascribed to the manifest difficulty of making effective national regulations without interfering with the inharmonious requirements of the laws of the various States.

In 1878 a bill was passed by both houses of Congress empowering the Surgeon-General of the Marine Hospital Service to frame rules and regulations for the purpose of preventing the introduction of contagious diseases into the United States, which rules and regulations should be subject to the approval of the President, but should not conflict with or impair any sanitary or quarantine laws or regulations of any State or municipal authority which then existed or might thereafter be enacted. One of the orders published under the authority of this act prohibited from entering any port of the United States all vessels from the Black Sea or Sea of Azof conveying rags, furs, skins, hair, feathers boxed or baled, clothing or bedding, or any similar articles liable to convey infection, and all vessels from the Red Sea or Mediterranean having on board such articles coming from Southern Russia. This aroused a storm of opposition on the part of the commercial interests. Nearly one thousand paper-mills were affected by the enforcement of the order, and their influence, thrown in the balance against the act, was mainly instrumental in modifying subsequent legislation. On the other hand, the American Public Health Association had for several years been considering and urging the advisability of Federal protection against the introduction of foreign pestilences. The yellow-fever epidemic of 1878 brought to the support of this association many able men who had witnessed the misery, panic, and complete cessation of business relations which had overtaken the Southern States during the summer of that year. Several bills were brought before Congress, all looking to uniform quarantine regulations under national supervision. One which appointed a director-general of health, charged with the duties of declaring quarantine at his own discretion in any part of the United States, and making and enforcing quarantine regulations, was lost in committee. Another, which appointed a board of health to frame the regulations, and a director-general to enforce them at any port where the local health-officer failed to execute them, was passed by the Senate, but was viewed unfavorably by the House of Representatives.

Ultimately, in March, 1879, an act was passed authorizing a National Board of Health, consisting of seven members, to be appointed by the President, not more than one of whom was to be from any one State, and four national representatives, detailed respectively from the Attorney-General's Department and the Medical Departments of the Army, Navy, and Marine Hospital Service. This board was required to obtain information on all matters affecting the public health, to advise the several departments of the Government, the executives of the several States, and the commissioners of the District of Columbia on all questions submitted by them, or whenever in the opinion of the board such advice would tend to the preservation and improvement of the public health; and in the discharge of these duties it was authorized to make or cause to be made such special examinations and investigations, at any place or places within the United States or at any foreign port, as it deemed necessary. It was also required to mature and report to Congress a plan for a national public health organization, the principal sanitary organizations and the sanitarians of the several States to be consulted in its preparation, with reference specially to quarantine, maritime and inland, and to the regulations which should be established between State or local quarantines and a national quarantine system. But before action was taken on this requirement the law of June 2, 1879, was enacted, imposing on the board certain duties in connection with quarantine. These were immediately undertaken, and the measures adopted were subsequently approved by the Academy of Sciences and the American Public Health Association, which advised against any change in the organization or methods. The board was required to make such rules and regulations as are authorized by the laws of the United States and necessary, for sanitary reasons, to be observed by vessels at their port of departure and on the voyage, when contagious or infectious disease was present at the said port; these rules, after approval by the President, to be published, communicated to, and enforced by the consular officers of the United States. As afterward framed, they required the exclusion from the vessel, as far as possible, of persons or things known or suspected to be infected; cleanliness, ventilation, and disinfection, if needful, preliminary to loading; and a sanitary or medical inspection prior to sailing, with the certification of the consular officer or medical officer of the consulate in the form of a bill of health. Vessels entering or attempting to enter any port of the United States without this bill of health, to show that they had in all respects complied with the requirements of the act, were to be subject to a fine not exceeding one thousand dollars. On its face this bill appeared to give the board a power over the sanitary condition of vessels coming to this country from in-

fected ports, by imposing a heavy penalty for the infringement of its rules; but a proviso, the effect of which was unforeseen, deprived the penalty clause of its force. To prevent the unwitting contravention of the law, it was provided that the penalty should not attach to any vessel until the act and the rules and regulations made in accordance with its requirements had been promulgated for at least ten days in the port of her departure. Under existing conditions of international comity, this promulgation of a United States law could not be effected at foreign ports, and but for the energy of our consular officers the intent of the law would have utterly failed. As it was, these officers at infected ports labored zealously to have all vessels clearing for the United States free from infection and in good sanitary condition. They had no support in their efforts, for vessels which had not complied with the law, as regards inspection and consular bills of health, very frequently found as ready admission into our ports, in the absence of infectious disease during the voyage, as those which had fulfilled the requirements of the law. Local quarantine authorities, if satisfied that the vessel was not a dangerous subject, permitted her to enter without reference to bills of health or other points connected with a national quarantine service. Nevertheless, much good was accomplished; for instance, the risk of importing yellow fever from Havana was much reduced by consular medical supervision over vessels sailing from that port, which supervision, although non-compulsory in character, was generally effected; and in the exceptional cases in which masters of vessels declined inspection, the quarantine authorities of the port of destination were notified by telegraph, and prepared to make special inquiry into the sanitary condition of such vessels.

Another section of the act under consideration required the board to co-operate with and aid State and municipal authorities in the execution of their rules and regulations, and authorized it to take steps toward strengthening the quarantine of ports at which existing regulations did not appear to give adequate protection. If there were no local regulations, or if these were defective, at any port, the board was called upon to report the facts to the President, who was authorized, at his discretion, to order the board to make rules and regulations for the port in question, to be enforced by the State authorities; but if the State authorities failed or declined to enforce them, the President was empowered to detail an officer or appoint a proper person for that purpose. Under this call to co-operate with and aid State and local boards, and in the exercise of the advisory duties imposed by its constituting act, the board, after full consultation with local health authorities and the sanitarians and commercial men of the country, drew up a system of quarantine rules, which it recommended for adoption at the various ports, and which were adopted by nearly all the local authorities, thus overcoming the difficulty of formulating rules which should not conflict with local laws. These rules recognized as contagious or infectious diseases, cholera, yellow fever, plague, small-pox, and typhus; as an infected port, one at which cholera, yellow fever, or plague exists, or at which small-pox or typhus prevails as an epidemic; and made use of the word quarantine as meaning *the administration employed to determine the presence or absence of the causes of contagious or infectious diseases in vessels arriving at a port, and to secure, if present, the removal or destruction of such causes.* They prescribed the accommodations and equipment of a quarantine station, and the general principles of detention for observation in the case of suspected vessels, and for medical and sanitary treatment in the case of infected vessels. Persons under observation for yellow fever were to be detained until, in the judgment of the local authority, they might be safely permitted to go on shore, but this period was in no case to be less than five days from the time of the last exposure. The period of incubation of the disease or diseases for which the ship was quarantined was to be held in view in considering the duration of the detention of persons who had been, or were supposed to have been, exposed to infection.

Also, in aid of the local authorities, certain refuge stations for infected vessels were established on the coast. One for ports on the Gulf coast at Ship Island, Miss., a second for the Southern ports on the Atlantic coast at Sapelo Sound, Ga., and a third in Hampton Roads. Under the law these were not national quarantine stations, but lazarets or refuges for suspected or infected vessels refused admission by the local authorities of ports which had no facilities for the accommodation of suspects, the treatment of sick, and the proper handling of infected ships and cargoes. These stations were of immense advantage to the coasts which they covered, each acting as a local lazaret for the many small ports which were incapable of supporting an institution of that character, rendering unnecessary a multiplication of infected foci, and affording, under national auspices, better care to the stricken vessels than had been available prior to their establishment. The principle was by no means new. The English quarantine law, as has been seen, required all infected vessels approaching the coast of the United Kingdom to proceed to the thoroughly equipped station at Milford Haven; and in this country the quarantine establishment of the port of New York had always been open to vessels bound for the ports of New Jersey and Connecticut, and the Boston station to vessels for other New England ports. But the system was peculiarly suited to the needs of this country, in view of the relations of the National and State governments with respect to quarantine, the latter wielding the power under the law, and the former restricted to aid and co-operation. The local authorities of ports within the range of the refuges were enabled to operate efficiently in the exercise of their quarantine powers, by concentrating their resources on the management of a service of inspection and observation which granted admission to port or sent the vessel to the national refuge station, as might be deemed best under the circumstances.

It was the intention of the board to establish refuge stations at certain points from Galveston to the Delaware Breakwater, that the whole line of coast might have readily available support. Each station was to be provided with places for loading, detaining, cleansing, and disinfecting vessels; hospital accommodations for the sick, and quarters for passengers and crews held under observation; wharves, warehouses, and fumigating houses for the handling of infected cargoes; steam-tugs, boats, etc., for the proper administration of the station; medical supervision and attendance, and the personnel needful to carry out the purposes of the establishment, with quarters for their accommodation. But these intentions were frustrated by the action of Congress in locking up the unexpended balance of the fund originally appropriated for such purposes. This appears to have been done under a misapprehension of the character of the proposed stations, which were at the time frequently spoken of as national quarantine stations, and must be construed as an expression of the disinclination of Congress to warrant national interference with State and local authority. The station established at Ship Island, Miss., for co-operation with the Gulf ports, was well outfitted with pavilion quarters and hospital, wharves, storehouses, boats, a steam-tug for boarding vessels, and a sloop for communication with the mainland. The Sapelo Sound station was in efficient working order, and gave much satisfaction to the quarantine authorities of Georgia and South Carolina, although much of its accommodation was of a rude and makeshift character. At Norfolk a barge was fitted up as a floating hospital for the relief of any infected vessel that might put into Hampton Roads for assistance.

The board was also required to co-operate with and aid State and local authorities in preventing the spread of epidemic disease from one State into another, and very shortly after its organization the Memphis epidemic called forth every energy for its limitation. During the epidemic of the previous year, 1878, self-preservation imposed the policy of non-intercourse on most of the Southern communities, and what was known as the shotgun quarantine was inaugurated: Vessels from New Orleans or other infected or suspected places were repelled from

the Mississippi landings by armed citizens, and trains and other overland modes of interstate communication were stopped at the State line and denied right of way. But under the auspices of the National Board of Health these rigorous quarantines were replaced by the system of medical inspection; commerce and travel were not interrupted, but placed under such a supervision that the disease was not propagated on their lines. According to the report of a Senate committee of the Forty-seventh Congress, the disease "was actually stamped out in New Orleans and confined to the limits of Memphis; and instead of the general disorganization and panic, with suspension of business, trade, and commerce which pervaded the country in 1878, commerce and communication with the infected cities were *regulated—not stopped*, or even retarded to any considerable extent—and the general business of the country went on in its usual methods and through its usual channels without serious interruption. Instead of panic and alarm, confidence and a sense of security pervaded the country." This system proved so efficient in restraining the spread of yellow fever, that in the following year its continuance was imposed on the board by the action of the States that were exposed to danger from the presence of the disease in New Orleans. As this city had been the starting-point for many wide-spread epidemics, its condition was narrowly watched by the health authorities of neighboring States, and on the acknowledgment of the presence of suspicious cases ordinances were passed prohibiting the landing of freight or passengers within their jurisdiction, unless these carried with them the inspection certificates of the national health service. At first the official announcement of the resident member of the National Board was accepted by the States as authoritative with regard to the condition of New Orleans; but as it was found that the city authorities were disposed to withhold information in suspicious cases, the mere rumor of a case of fever sometimes precipitated the action of the States in their demand for National Health Board inspections as a guarantee of safety. New Orleans acknowledged the advantage of these inspections in permitting commercial intercourse which would otherwise have been stopped during the existence of fever, but objected to the imposition of any restriction, delay, or inconvenience until the disease was acknowledged by its own authorities. The desire to suppress all suspicion of infectious disease in its line of operations is as old as commerce itself. De Foe, speaking of the last and greatest epidemic of plague in London, says that, early in May (1665), it "had gotten into several streets, and several families lay all sick together, and accordingly in the next weekly bill the thing began to show itself; there was, indeed, but fourteen set down for the plague, but this was all knavery and collusion, for St. Giles parish buried forty in all, most of whom it was certain died of the plague." The Mississippi States did not have that confidence in the official statements of the health authorities of the city of New Orleans that they were ready to give to the National Board of Health, which represented their interests in the suspected city. During the continuance of yellow fever in the city every vessel, with its crew, passengers, and cargo was inspected before sailing, and similar precautions were taken on the lines of rail. Refuge stations were established at points on the river below Memphis, Tenn., and Vicksburg, Miss.; at Cairo, Ill., and Bayou Sara, La., at which vessels were inspected in passing and their bills of health *viséd* for free admission into their port of destination, or detained for appropriate treatment if yellow fever was found to have been developed during the voyage.

The law which imposed on the National Board of Health the duty of aiding and co-operating with State and local authorities expired at the end of four years from its passage. It was tried as an experiment, but although successful, certain influences were at work to prevent its perpetuation. Chief among these was the desire of the Marine Hospital Service to erect itself into a bureau of medical officers of the Treasury Department similar to that of the Army or Navy. The law of 1878, repealed in 1879, placed the so-called national quarantine in the hands of this service, and from that time it has made every effort to recover its lost position and constitute its members federal quarantine officers, paid from the national treasury, instead of hired medical attendants, paid for their services to sick sailors from a fund contributed by the mercantile marine. The board was represented as merely a medium by which State and local authorities dipped their hands into the federal treasury, and the antagonism of the New Orleans board was magnified into inability to co-operate with the local sanitary authorities of the country; while the Marine Hospital Service was upheld as having a medical staff, hospitals, revenue cutters, etc., all of which could be used for quarantine purposes without calling into existence any new machinery such as a National Board of Health. These arguments, shallow as they were, sufficed to prevent the re-enactment of the so-called quarantine law, yet failed to carry congressional action so far as to make the Treasury Department the administrator of a national quarantine. The expedient was adopted of placing an epidemic fund in the hands of the President, to be used in aid of State and local boards of health, or otherwise at his discretion, in preventing and suppressing epidemics and maintaining quarantine at points of danger. The disposition of this fund has been transferred to the Treasury Department, and of late years the current expenses of the refuge stations established by the National Board of Health have been paid from it by the Marine Hospital Service.

Other than the law passed at the end of the last century, requiring revenue, marine, and custom officials to aid in the enforcement of local laws, and an appropriation in the sundry civil bill of each successive year, to be used in case of an epidemic, there is at present no national legislation for the protection of the country from invasion by exotic disease. Several efforts have been made by State and local boards, and such sanitary organizations as the American Public Health Association, and the Sanitary Council of the Mississippi Valley, for the rehabilitation of the National Board of Health; but these have failed, and the country is now in no better condition as regards national legislation than it was during the epidemic of 1798, which devastated Philadelphia and New York, and prevailed even in Boston and other New England towns.

The need of a central health organization as a bond of union between the State authorities, and a means for co-ordinating their action and representing their interests on the international aspect in the case of a threatened invasion of cholera or yellow fever, has been so well appreciated by these authorities, that, having failed through the opposition of the Treasury in their efforts to secure the re-establishment of the National Board of Health, they endeavored to obtain from Congress a central health authority of some kind, urging at first a board constituted by State representation, and when that was declined on the ground of unwieldiness, asking with equally negative results for a director-general of health; yet ready to be satisfied with any legislation that would enable them to realize the benefits of co-operative action such as were obtained under the auspices of the National Board of Health. Meanwhile this board continues to have a legal existence, as the limitation of four years applied only to the so-called quarantine law, not to the constitution of the board. It requires merely the financial support of Congress to enable it to resume the labor of amalgamating into a trustworthy whole the inspection or quarantine systems that protect the coast, and the salient points of interstate travel and traffic.

Charles Smart.

QUASSIA, U. S. Ph.; *Quassiæ Lignum*, Br. Ph.; *Quassia de la Jamaïque*, Codex Med.; *Lignum Quassiæ*, Ph. G. (including also wood of *Q. amara*). The wood of *Picræna excelsa* Lindley; order, *Simarubaceæ*. A large, fine-looking tree, with erect, thick trunk and spreading branches covered with a rather smooth brownish-gray bark. Leaves alternate, odd-pinnate, leaflets entire, oblong, pointed, thick, and smooth. Flowers

small, in lateral cymes, polygamous, greenish-yellow. The perfect ones have a calyx of five minute teeth, five petals, five stamens about as long as the corolla, and two or three one-ovuled carpels with their styles united. The staminate flowers have more spreading petals and longer stamens, no pistils. The carpels ripen into purplish-black drupes. Jamaica Quassia, also called Bitter Wood or Bitter Ash, from its resemblance to that tree, is a native of some of the West India islands, from several of which the wood is exported, especially from Jamaica.

Originally the name was applied to the wood of *Quassia amara* (*Bois amer de Surinam*, Codex Med.), a shrub belonging in the same family and possessing exactly the same qualities, growing in Central and South America, and first introduced into Europe about the middle of the last century. The present tree was generally substituted for *Q. amara* in the early part of this century, although the other is still found in European pharmacies. *Q. amara* is rarely to be found in American or English shops.

FIG. 3226.—Flowering Branch of Quassia (Picræna excelsa). (Baillon.)

Quassia is imported in billets or logs several feet long, and from two to six inches in diameter. It has a dark-gray bark, and tough, compact, yellowish-white, inodorous, but very bitter, wood. These logs generally go to turners, where the best are cut into drinking-cups or goblets, and the pieces are saved for the pharmacies. Otherwise the logs must be cut or rasped into fine pieces to make them suitable for pharmaceutical handling. These shavings are yellow, inodorous, and intensely and persistently bitter.

COMPOSITION.—The bitterness of Quassia is due to a minute quantity of a neutral crystalline substance, first obtained in 1835 by Winckler from the wood of *Q. amara*, and afterward from that of the Picræna now used. *Quassiin* is sparingly soluble in water and alcohol, has an exceedingly bitter taste, and probably represents the tonic and "narcotic" properties of the crude drug. Quassia contains no tannin.

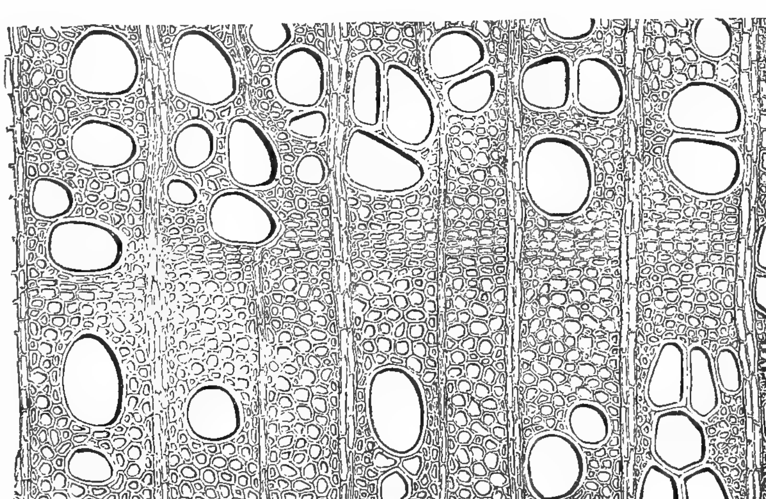

FIG. 3227.—Section of Quassia Wood. (Baillon.)

ACTION AND USE.—Quassia is generally regarded as a pure or simple bitter tonic, like gentian, and is mostly used as such, being given, either alone or in combination with aromatics and stimulants, as a stomachic and appetizer. In debility, in convalescence from fevers, in dyspepsia, it has been and is still in considerable use. Its taste is, however, more bitter and disagreeable than that of gentian or quinine, and on this account alone would be less desirable as an appetizer than they. Quassia is, in addition, poisonous to insects and fishes, and probably in a slight degree to other animals. The symptoms produced by it are stupor, convulsions, paralysis, etc. It does not appear to be deleterious to man. Another useful employment of the drug, depending upon this insecticide or vermicide power, is as an injection for ascarides, for which purpose it is both safe and efficient.

ADMINISTRATION.—Dose: One or two grams (gr. xv. ad xxx.) in infusion. The officinal preparations are Tincture (*Tinctura Quassiæ*, U. S. Ph., $\frac{1}{10}$), Fluid Extract (*Extractum Quassiæ Fluidum*, U. S. Ph., $\frac{1}{1}$), and Extract (*Extractum Quassiæ*, about $\frac{30}{1}$); the latter is useful for administration as pills. The "Quassia cups" are medical toys of no great value. For injection as a vermicide from half a pint to a pint of a ten per cent. infusion may be used.

ALLIED PLANTS.—Besides three species of *Picræna*, all bitter, the order contains *Quassia amara*, above noted; *Q. cedron* H. Br., and *Simaruba officinalis* D. C., both of which contain the same bitter principles and are in the Codex. It also contains the *Ailanthus glandulosa* Desf.

ALLIED DRUGS.—For tonics see GENTIAN, for anthelmintics see KOOSSO. *W. P. Bolles.*

QUEBRACHO. This name is given in portions of Central and South America to several different trees whose wood or bark is mostly used in tanning; of these that known as white or pale Quebracho (*Quebracho blanco*), is the only one of special medical interest. It is *Aspidosperma Quebracho* Schlecht., order, *Apocynaceæ*, and is also used in tanning. It is a large-sized tree, with slender, drooping twigs; small, opposite, or whorled (in threes), short-petioled or sessile, elliptic-lanceolate, pointed, leathery, bluish-green leaves; numerous axillary clusters of small yellow flowers, and large elliptical, woody capsules (Lüerssen). It is an inhabitant of tropical South America; the bark is exported from Brazil, where it is valued as an antiperiodic.

Quebracho was first brought to medical notice in Eu-

rope, about ten years ago, by Dr. Penzoldt, as a cure for asthma. The bark, which is the portion employed, comes in thick, coarse pieces, of a yellowish-brown color, and bitter taste. It contains an abundance of *tannin*, and six alkaloids: *Aspidospermine*, crystallizing in needles, soluble in about fifty parts of alcohol, one hundred of ether, and six thousand of water—a weak base of bitter taste; *Aspidospermatine*, in warty crystals, more soluble; *Aspidosamine*, amorphous or partly crystalline; *Quebrachine*, colorless crystals becoming yellow in the light; *Hypoquebrachine*, yellow albuminoid masses; *Quebrachomine*, resembling quebrachine. These alkaloids all weaken respiration and circulation, and most of them are general paralyzers of motion. All nauseate somewhat; aspidosamine is decidedly emetic; quebrachine is most efficient in its effect upon the breathing; *aspidospermine* is similar, but weaker. Quebracho, and the two last-named alkaloids, have been employed to reduce the dyspnœa of asthma, cardiac disease, phthisis, etc., with some reputed success; but although considerably tried and advertised several years ago, they are almost never called for at present; they appear to have done the most good in asthma. Dose, two or three grams (gr. xxx. ad xlv.), in form of tincture or infusion; of the alkaloids quebrachine or aspidospermine from two to three centigrams may be given.

Allied Plants.—The genus *Aspidosperma* contains upward of forty species, mostly South American. The order is not an important one; it contains a few, not valuable medicinal, and some poisonous, plants. *Alstonia scholaris*, etc., the *Apocynums*, *Strophanthus*, *Nerium*, and *Vinca*, are examples.

Allied Drugs.—Morphine is probably more reliable as a respiratory depressant, and has also a great advantage over quebracho of stilling pain besides.

W. P. Bolles.

QUEEN'S ROOT (*Stillingia*, U. S. Ph.). The root of *Stillingia sylvatica* Linn., order, *Euphorbiaceæ*, a perennial plant, with a large, woody root, and erect herbaceous or slightly woody stem, a foot or so in height; leaves large, thick, oval, or lanceolate, finely serrate; inflorescence a thick terminal spike. Flowers unisexual, the female, few at the base of the spike, solitary, each in the axil of a thin, broad scale, with a large gland at each side, consist of a three-lobed calyx, three-celled ovary, and three styles; the staminate flowers are numerous, clustered in the axils of similar bracts all the way up the axis; they consist of a minute cup, from which emerge two partly united stamens. Stillingia grows abundantly in the Southern States, and has been used there, and a little elsewhere, for about half a century.

The root is "about twelve inches (30 centimetres) long, and nearly two inches (5 centimetres) thick, subcylindrical, slightly branched, compact, wrinkled, tough, grayish-brown, breaking with a fibrous fracture, showing a thick bark and porous wood: the inner bark and medullary rays with numerous yellowish-brown resin-cells; odor peculiar, unpleasant; taste bitter, acrid" (U. S. Ph.). The composition of stillingia is not well known; *essential* oil and *resin* appear to be present. It is an emeto-cathartic, like many other plants in the order, and is also said to be "alterative." Upon this property its principal use depends. It is considerably used in "scrofula," late syphilis, and other chronic complaints, with reputed benefit. Dose, one or two grams (gr. xv. ad xxx.) two or three times a day. A fluid extract is officinal (*Extractum Stillingiæ Fluidum*, U. S. Ph.).

Allied Plants.—Another species of *Stillingia* yields the Chinese "vegetable tallow." For the order see Castor-oil.

Allied Drugs.—Sarsaparilla *et id omne genus;* Poke Root, Bitter-sweet, etc. *W. P. Bolles.*

QUINCE SEED (*Cydonium*, U. S. Ph.; *Coing*, Codex Med.). The seed of the garden quince—*Cydonia vulgaris* Persoon—order, *Rosaceæ*, an Asiatic shrub cultivated in Europe for many centuries, and now grown in most warm, temperate countries. The fruits contain

malic acid, *pectin*, *mucilage*, etc., and have a peculiar flavor, due, perhaps, to *pelargonic ether*. The seeds are valued for their *mucilage*, and have been long in use in Eastern countries. They also contain a trace of *hydrocyanic acid*. Quince seeds grow eight, ten, or more in each cell—they are smaller and more irregular in shape than apple seeds—have a dull surface, and are agglutinated together. They contain about twenty per cent. of a pe-

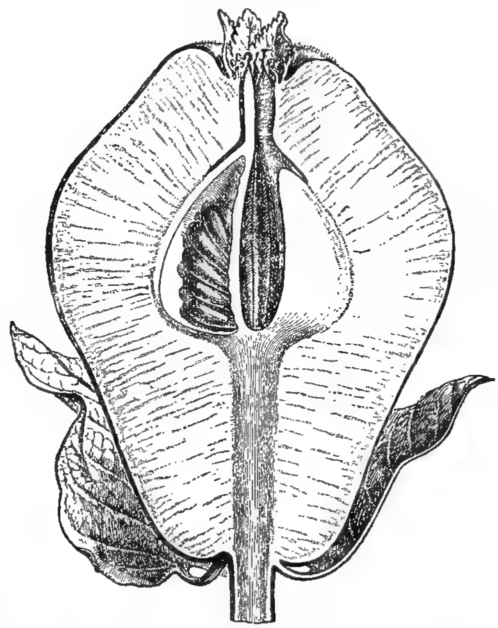

Fig. 3223.—Garden Quince: Section of Fruit. (Baillon.)

culiar mucilage, capable of gelatinizing more than one hundred parts of water, but of little adhesive power; it consists of a soluble acacia-like portion, and an insoluble part having many of the characteristics of cellulose. The officinal mucilage is made with two per cent. of seeds. Quince seed may be put to the various uses of mucilages in general, demulcent drinks, *collyria*, surgical dressings, sizing, etc.

The principal demand for it, within the past few years, has been for toilet purposes (dressing the hair).

Allied Plants.—See Roses.

Allied Drugs.—See Gum Arabic. *W. P. Bolles.*

QUINTO is a spa in the province of Saragossa, Spain. There are two springs, of similar composition, the waters of which are employed, as a rule, only internally. The two springs are known as the Upper and the Lower. The following is the composition of Quinto water, according to the analyses of Moreno and Lletget, quoted by Rotureau in the "Dictionnaire Encyclopédique des Sciences Médicales."

One litre contains:

	Grammes.
Calcium sulphate	1.759
Sodium sulphate	0.498
Magnesium sulphate	0.307
Magnesium chloride	0.014
Sodium chloride	0.009
Calcium chloride	0.005
Silicic acid	0.010
Total	2.602

These waters enjoy considerable reputation in Spain in the treatment of syphilitic affections. They are also employed in digestive troubles and for the relief of those suffering from uric-acid gravel. The waters are both diuretic and laxative. The season extends from the first of June to the end of September. *T. L. S.*

RABIES. (Gr., Lyssa; Lat., Rabies; Germ., Hundswuth, Tollwuth; Fr., Rage, Hydrophobie.) Rabies, or, as it is more commonly designated in our language, hydrophobia, is to be classed essentially among the more pronounced neuroses. It is thought to be occasioned only by the specific poison from rabic animals, and its principal phenomena are connected with an exalted reflex irritability, chiefly of the respiratory nervous centre, and the centre of deglutition; later, there are increased irritability of the motor spinal centres, general hyperæsthesia, and, finally, psychical exaltation. Lyssa is therefore to be regarded, from its symptomatic characteristics, as a specific toxic affection, and is essentially a variety of tetanus, similar in some degree to that caused by strychnia. It is placed in the list of those diseases which, for want of a better classification, may be called "tetanici."

Rabies seems to belong to the same class of diseases as erysipelas, anthrax, etc., in that it depends for its transmission upon inoculation into the blood, or at least into the subcutaneous tissues of the animal body. It presents many points of similarity with many of the bacterial forms of disease, in which the infecting agent is known to invade the body, and there multiply, and by its increase to produce the phenomena of the disease.

True rabies (lyssa vera) arises in all instances from infection by the specific virus, or that material substance which contains or conveys the infecting principle, as produced in animals affected with this malady.

Rabies in man is not known to have ever occurred except after penetration of the rabic poison beneath the epidermis, or other epithelial covering of the body. There is no known case in which it has been actually proved that infection has taken place through the uninjured mucous membrane, although cases have been reported in which this has been thought to occur. These cases are either due to a mistake in diagnosis, or to the fact that slight lesions of the mucous membranes are easily overlooked, or may be quite healed before the disease makes itself evident.

As a proof of the protection afforded by the mucous membrane against the entrance of the rabic virus into the animal system, is the fact that the flesh and milk of animals affected with this disease have been used as food by the human subject without the slightest ill effects. This fact accords with the further fact, that the milk and butter from cows which are the subjects of rabies may be taken with impunity.

The sole avenue of entrance of the rabic poison is, therefore, by the path of infection, and this means the inoculation of the disease.

Rabic infection may take place in various ways: First, from the teeth or the bite of a diseased animal. This is not dangerous unless the teeth have penetrated the epidermis, or at least have eroded or abraded it, and by this means a path of entrance has been made for the saliva to reach the subcutaneous tissues. There is reason to believe that the virus is dangerous at a period somewhat previous to the development of the marked signs of rabies in the dog. The danger is proportionally increased as the teeth of the dog are sharp, and the wound is deep and penetrates the flesh to a greater degree.

The power of communicating the disease is not confined to the periods of fury, which are a feature of the malady in the dog, but the rabic animal is prone to become suddenly furious from a state of absolute quiet, in which the existence of a serious disease could not be suspected, and may then inflict a fatal bite.

The clothing, or other covering of the body, affords a limited degree of protection from the poison of rabies, as the passage of the teeth of an animal through the clothes removes the saliva to a more or less perfect degree.

The claws of any of the carnivorous animals may be the bearers of the rabic poison, from the fact that they are more or less in contact with the mouth of the animal, and are likely to become contaminated with the saliva. A slight scratch would be sufficient to afford entrance to the infection. The disease may also be communicated by the tongue of the rabid animal, in licking any place from which the epithelium is absent, which thus allows the virus to come into contact with the subcutaneous tissues.

Second. Another source of danger is the flesh or blood of animals dead from rabies, which constitutes a peril to those who may be employed in the disposal of the bodies, or in making post-mortem examination, of such animals. The smallest excoriation or abrasion is sufficient for the infection of the system, and thus for the introduction of a fatal disease.

Etiology.—The etiology of rabies (lyssa humana) is uniformly and invariably the inoculation of the system with the specific poison of the disease, derived from an infected animal—dog, cat, fox, wolf, horse, skunk, cayote, the ruminants, swine; and in one case observed by the writer, the disease followed the bite of a rabbit, which was not known to be affected. It is not definitely known that other species of animals are capable of communicating the infection of rabies.

Like anthrax and many other infective disorders, the inoculation by rabies always takes place through some wound or other defect of the skin or mucous membrane; and the disease is communicable only by means of introduction of the virus into the subcutaneous tissues. The virus is contained not only in the saliva of diseased animals, but also in other glandular secretions, in the blood, in the substance of the nervous structures, and probably in all the tissues of the body.

Rabies is uniformly dependent upon infection from without, and in nearly all cases the disease is communicated by means of the bite of a rabid animal. The period of incubation of this disease, *i.e.*, the length of time after the introduction of the virus into the system before the symptoms of rabies make their appearance, is a variable one. It has been known to become evident within the first day after inoculation, and it is sometimes delayed in its appearance for months, or even years. The most frequent period for the invasion of the disease is at a time from three to eight weeks after inoculation.

There appears to exist in rabies, as in syphilis, a period of latence of the infectious material, during which it may be retained within the system, but shows no symptoms of its presence. At times the disease appears to cause prodromal symptoms in the original seat of the infection, such as pain, swelling, etc., with restlessness and anxiety on the part of the patient; but often the malady appears suddenly in the form of well-marked disturbance in swallowing, or the initial symptom may be a convulsion of the respiratory apparatus following an attempt at swallowing. Death is usually inevitable, generally occurring between three and six days after the first onset of the symptoms of the disease. The fatal result may even occur in so short a time as twelve to twenty-four hours. The temperature of the body is elevated, at times reaching 40° C. (104° F.). Death follows from apoplexy, asphyxia, exhaustion, or the patient dies suddenly from some unknown interference with the vital processes. Not all patients who are bitten by rabid dogs are attacked by rabies; the predisposition of the patient to infection of any kind has much to do with the severity of the symptoms in many cases. The most important features of any case are the location, and still more the depth, of the bite. Lacerations by the teeth of the rabid animal, which are situated upon unprotected parts, and especially those which penetrate deeply, are most dangerous.

Incubation.—The dreaded character of the rabic disease, and the great variability which exists in regard to the time of its appearance after the poison has entered the system, have led to the more careful obervation of cases in which there was supposed to be danger of this malady, with the result of obtaining more definite and uniform information as to the time and the manner of the symptoms which usher in the rabic development. It has been noticed that local sensitiveness, with a gradual extension from the extremity toward the trunk, occasionally precedes the outbreak of the disease, accompanied by renewed pain in the scar of the bite, or in the bite itself, if this be not already healed, with redness and swelling of the neighborhood. Often there is prodromal rest-

lessness, with physical depression, febrile action, etc., though in some cases the spasm in deglutition is the first noticeable symptom of the invasion of the disease. Recently M. Pasteur, of Paris, has made all the known authentic cases of undoubted rabies which have occurred in France, the subject of careful analysis as to the period which elapsed after the inoculation of the disease, before the invasion of the symptoms of the fatal malady. He collected data concerning 537 cases. Of these, 27 were excluded from one cause or another, leaving 510 cases as the basis of his deductions.

These 510 cases show an average period of incubation of 72 days, which is divided among the cases in the following manner: In men the period of incubation was found to be 80 days on the average; in women it was, on the contrary, only 65 days. The period of latency in men is, therefore, 15 days longer than in women. In persons between the ages of two to fourteen years, the latent period was 20 days shorter than in persons between fifteen and seventy-eight years (women, 57 days; men, 76 to 77.5 days, respectively). This apparent difference may possibly be accounted for, in some degree, by the fact that in children the wounds produced by a rabid animal are more likely to be located upon the face or other uncovered parts of the body, and thus inoculation of the patients may take place more easily; and possibly the violence of the succeeding phenomena may also be thereby materially augmented.

It is found that in cases in which the injuries were seated upon the head and neck, the period of incubation was 55 days; while in those cases in which the wounds were situated upon the upper extremity it was 81, and on the lower extremity it was 74 days; while in such cases as presented injuries of many parts of the body, among which were wounds about the head, the period of incubation was 55 days.

Persons who have been bitten by rabid wolves, to the number of 49, presented a period of incubation of 39 days; those bitten by dogs, 293 cases, a period of 73.5 days; and those bitten by cats, 31 cases, a period of 80 days. Pasteur had already called attention to the shorter period of incubation in cases of inoculation from the bites of rabid wolves.

The period of incubation is not modified in any way by any mode of treatment, neither is the duration of the disease, when it is developed, in any material way modified by the longer or shorter period of latence of the poison in the system. It is found that in seventeen per cent. of all cases of rabies the period of incubation is three months or over.

Pasteur states that the disease shows itself, in the majority of cases, at a period between the fortieth and sixtieth days after the reception of the bite.

Diagnosis.—The most prominent symptoms of rabies are referable to the nervous system, and consist of an exaltation of the reflex irritability, especially of those departments which control the power of deglutition and the phenomena of respiration. These symptoms are soon followed by the development of an abnormal degree of nervous irritability of the spinal motor centres, by general hyperæsthesia of the entire body, and finally by pronounced mental and moral disturbances.

The classical and only indispensable symptom of human rabies consists in the frightful and recurrent spasm which is induced by attempts at deglutition, by the presence of saliva in the pharynx, by efforts at deep inspiration, as well as by the slightest irritation of the skin from any cause, and also by the movements of the atmosphere, in which the slightest breeze is caused, or at least felt, especially if the temperature of the external irritant or of the air be much below that of the body of the patient.

The fact that the attempt to swallow is productive of great distress, and that it induces the spasm, causes the utmost terror in the mind of the patient at the thought of deglutition. This induces the fear of fluids so characteristic of this disease. It is the pain and distress thus occasioned which constitute the real source of the "hydrophobia," the fear of the painful spasm of respiration and deglutition which the effort of swallowing induces.

The term "hydrophobia" is the origin of much needless confusion, for not only may a fear of the effort required to take liquids be present, without the existence of rabies, but the rabic disease may be developed in fatal intensity without the occurrence of the spasmodic symptoms usually associated with rabies. Hydrophobia alone does not constitute rabies, and rabies may exist without "hydrophobia." In fact, in canine rabies, the hydrophobia is not a prominent or a frequent symptom. We should understand by the term "hydrophobia" a condition which may be thus delineated: First, one in which, without apparent motive, the patient finds it impossible to swallow liquids, and which may or may not be accompanied by disagreeable or painful sensations to the patient; second, the sensation of fear or terror at the sight or sound of fluids, even when the patient may be able to overcome this feeling so as to take fluids voluntarily as drink. Patients with rabies are frequently found in a state of great excitement from the fact that the fatal character of this disease is well known, but the patient can always be restored to proper consciousness by kindly and calming efforts on the part of those about him. Hydrophobia, therefore, constitutes only a symptom common to several distinct diseases. It is the product of an abnormal excitation of the nervous centres, or the nervous elements, either of direct or of reflex origin; or it is due to the disturbance of the normal relations existing in the tissues, which may be of three varieties: 1, a disturbance of the nutrition of the member or part; 2, the effect of a direct irritant; and 3, the disturbance of the nervous supply, or of its distribution in the part affected.

The "hydrophobia" (fear of water or other fluid) is apparently due to an affection of the general nervous system, for the hydrophobic spasm is present before the patient attempts to drink; and it may be provoked by a variety of causes, such as a bright light, the view of an unexpected or unusual object, a sudden noise, a touch from an unfamiliar substance, or even the movements of those about the patient or the impression produced by a draught of air.

The last is one of the most important symptoms of true rabies (Lyssa vera), as it is never absent in the real disease, and is seldom present in any of the other affections which are associated with or accompanied by spasm of deglutition. It is indicative of communicated rabies.

The excessive tension or the exalted reflex irritability in the nervous centres, or in those nervous centres which are concerned in respiration, is the essential character of the rabic development in man. The augmentation of the excitement by the indispensable requirements of the animal (human) organism (air, water, etc.), and the discharge of nervous force in the way of powerful contraction of the muscles controlled by the nerves of respiration and of deglutition, constitute the symbols of the disease. These pathognomonic conditions constitute the means of distinguishing rabies from any other condition of the system which may be accompanied by hydrophobia (Jaccoud).

The terror, the maniacal fright, the convulsive cries, seem to be provoked by any agitation of external objects in a manner to impress any of the special senses. It would seem that the entire nervous system, the general sensibility, as well as the special senses, the intellectual faculties, and the moral nature are in a state of superexcitation, so that the least irritation of any part is communicated to the entire system by a kind of special reflex action, and produces the convulsive explosion.

There seems to exist a special hyperæsthesia, which does not manifest itself at the seat of contact, as is usual in such conditions, but which is reflected to remote centres, and there produces an explosion of force in the form of painful spasm, cramps, convulsive contortions, and delirium of varying intensity, often associated with cries, fury, terror, visions, hallucinations of the special senses, etc.

The symptoms of rabies are at times very confusing, and have given rise to the two designations, "hysterical hydrophobia" and "hydrophobic hysteria," both of which conditions undoubtedly exist, and render the diagnosis

of the actual state of the patient more or less difficult, and frequently prolong the period of uncertainty as to the precise nature of the malady. The exalted mental excitability of the patient exaggerates the already existing irritability, and the spasm is at length induced by the sight or the sound of fluids, and finally is aroused by the simple thought of liquids or of drinking. The anxiety of the patient is increased by the well-known fatal character of the malady, and is too often unnecessarily and cruelly augmented by the injudicious and senseless conduct of those about the patient; and in those cases in which the fear of the disease leads to the improper or brutal treatment of the sufferer, which has often occurred, there is frequently a condition of absolute mania. Calm and gentle measures will, however, always recall the patient to a consciousness of himself and his surroundings.

The diagnosis of rabies in the human subject may be rendered difficult or temporarily impossible from simulation of the disease by Lyssa falsa, seu nervosa. This is a condition which is frequently induced by the fear of rabies, and usually follows the innocent bite of an animal free from the disease. The diagnosis cannot long remain the subject of doubt, as an interval of a few days—never longer than six—will suffice in all cases to definitely establish or to disprove the existence of the disease.

Lyssa falsa may occasionally be followed by a fatal termination, owing to the anxiety of the patient, as has frequently been observed in neurotic individuals, after the bite of a healthy animal, and even after the accidental bite of the human subject in cases in which there could be no suspicion of rabies.

These rare cases may, perhaps, be classed as tetanus, or as tetanus traumaticus lyssoides, as has been suggested by Lorinser.

The result of rabies is invariably fatal, and usually occurs within three days after the appearance of the disease. Occasionally the life of the patient is prolonged until the fifth or sixth day, but this is exceptional. In the human being the first symptoms of the fatal attack seem to be a peculiar itching of the old wound, and the spread of neuralgic pains from it toward the nerve-centres. A general feeling of malaise, and an impending dread of something frightful about to happen, a tightness about the throat, are among the common complaints of the sufferer, and there is difficulty in swallowing; breathing becomes affected, and there is oppression over the whole chest. Violent paroxysms follow, showing evidently that the whole nervous system is in a frightfully excited state. A ray of light, a breath of wind on an exposed part of the body, the sight of water, the constriction following the attempt at swallowing any fluid, greatly craved though it may be, are sometimes sufficient to determine the spasm. Ropy, viscid mucus is secreted by the salivary glands, and vehemently expelled from the mouth. Violent convulsions of the muscles of the larynx and pharynx take place in many cases, closing the windpipe and preventing the access of air. Hallucinations come on, and sometimes wild delirium. During the interval between the attacks the sufferer is often calm and rational, and, in many cases, feeling the approaching access, he begs to be restrained so that he may do no harm. Paralysis finally supervenes, and the sufferer, totally exhausted, is mercifully relieved by death. The fatal result may occur in a short time (from twelve to thirty-six hours). In other cases the disease steadily advances to a severer form, the temperature rising to 40° C. (104° F.). Death usually takes place then from apoplexy, or from asphyxia, or the patient may suddenly expire, even when improvement may seemingly have occurred.

The following vivid description of the progress of human rabies is taken from the *Archives de Physiologie*, February 15, 1887. It is from the pen of M. J. Girode. The patient was treated in the Hôpital Beaujon, by M. Guyot. The case belongs to that form in which the symptoms are developed with great rapidity, and is classed as "presque foudroyante." The clinical history is as follows:

Henry B., twenty-eight years of age, Italian, entered the hospital April 10, 1886. He has always been well. His character is of an impressionable nature, and he is decidedly nervous. He has been unfortunate in his affairs, and has practised as a musician, an actor, and a model in a studio. Has used intoxicating liquors somewhat to excess. He had a small slut dog, which was of very gentle disposition, but which bit him on the right hand, some two months ago, in consequence of a slight punishment. He compressed the wounded fingers in order to encourage bleeding for the time being; but thought no more of the matter. On the same evening the dog became morose, remained crouched in a corner, and died in the space of three days, without having taken either food or drink. These events occurred between February 10th and 15th, 1886.

In spite of their very suspicious character no one thought of these symptoms as indicating any dangerous condition, either of the dog or of the wound made by the bite in the patient's hand.

Until April 9th the patient remained perfectly well and strong. On this date he awoke with a severe headache; went, however, to his daily occupation; was hardly able to take any food at dinner, but still continued his work. Toward two o'clock he began to feel weak and feeble. One of his companions offered him some drink, but he pushed the glass violently from him, and was for a few moments in a state of collapse, without, however, wholly losing consciousness. He went to his home about three o'clock on April 9th, remained there until the 10th, at four o'clock, at which time he presented the following symptoms: headache, absolute sleeplessness, with periods of great restlessness, noisy delirium, moderate flow of saliva, absolute inability to swallow either liquids or solids, an overpowering sensation of constriction of the neck, with brief periods of great irritability during which he refused to see his friends, who were endeavoring to calm him and to restrain him from leaving the bed.

On arrival at the hospital the patient was seen to be a remarkably strong and well-built man, tall, with powerfully developed muscles. The face was pale, the features animated, the eyes bright and moist, the eyelids widely opened at times, giving the facial picture a strange appearance which might almost be called terrifying. He was sitting on the bed, calm, and remained quiet while the examination of his condition was being made. The patient had entire control of himself, and the mind was clear. His replies were correct; his chief anxiety seemed to be that he should be relieved from suffering; he spoke frequently of his children and of his mother. In spite of his loquacity it was possible for him to remain still, and he could assume a reclining posture without discomfort.

The two most striking symptoms at this time were the following: While in the middle of a sentence the patient would suddenly stop, as if seized by a severe spasm of the pharynx. If this occurred in the middle of a word, the remainder of the word was prolonged into a harsh guttural sound. The patient choked, threw the head strongly backward, and pressed his hands upon the throat. This condition lasted some minutes, and usually ceased with the expectoration of a small quantity of white, frothy mucus. The patient at once became talkative, and insisted that he should be bled, in order to relieve the pressure about the throat. The pharyngeal spasms recurred at intervals of five to ten minutes, and were more frequent if the patient talked.

Although the patient was consuming with thirst, and was constantly asking for drink, it was impossible for him to swallow anything. He was able to take the glass in his hands and look at it; but on the attempt to bring it to his lips his head was at once turned away. If the effort was made to force him to drink, he was immediately seized with a violent spasm. The glass was then covered with cloth, so that the patient could not see the liquid; but the result was the same. The repulsion for solids was equally marked. The cutaneous sensibility was everywhere diminished. In administering a hypo-

dermic injection of morphia there was no manifestation of sensation on the part of the patient, least of all any sign of pain when the puncture was made.

There was no exaltation of the senses, and the patient had no hallucinations. He exhibited no tendency to violence, either toward himself or toward others. During the paroxysms, and in the agony of an attack of cramp, he cried out for relief, and called for poison ; but on the relaxation of the distress the longing to live returned. The skin was moist; temperature, 38.2° C. (100.7° F.); pulse, 116, soft and fluttering. There was manifest cardiac erethism. The tongue was moist ; there was no appearance of vesicles upon it. Bowels constipated, and there was no vomiting. Urine was passed naturally ; it was little colored, transparent, and contained neither albumen nor sugar. There was no sign of disturbance in relation to the genital apparatus.

During the night of April 10th to 11th the patient was very restless, obtaining absolutely no sleep, even by the aid of morphia and chloral. On the following morning he was a little more tranquil, but the sight of persons or things about him began to terrify him. He was still more talkative, pictured his sufferings in frightful colors, and demanded to be instantly cured. Were it not for the recurrent pharyngeal spasm, which preserved the same character and the same frequence, the appearance of the patient did not materially differ from that of a nervous person who is excited on account of some recent accident. The skin was still moist ; pulse, 120 ; temperature, 38.4° C. (101.1° F.). Urination was normal, and there were no signs referable to the genital organs.

At eleven o'clock the patient complained that he was left alone ; his agitation was more pronounced; his sufferings were more agonizing. At times he was suffocating from the severity of the pharyngeal spasm, sprang from the bed, and rushed to the window for air. The expression of the countenance was much changed. There was no tendency to become violent or to bite. On two occasions the patient begged his attendants to retire, as he felt that he was about to lose control of himself. The periods passed without any attempt on his part to bite, or to bring anything near the mouth or teeth. Respiration at this time was jerking and hurried.

The disposition of the patient was affectionate, and he constantly spoke of his family and friends.

The dysphagia was persistent and complete. The patient took the glass filled with water, and made repeated efforts to bring the liquid to his mouth by closing the eyes and turning the head, but was unable to approach the cup to the lips. The attempt was made to introduce liquids through a tube. As soon as a few drops had passed into the mouth, the whole was suddenly expelled by a spasm of suffocation of extreme violence. The thirst was most intense, and the patient frequently tried to take liquids by bringing a small amount in contact with the tongue, but he was unable to do so. The skin continued moist. No urine had been passed since early morning. Stool absent.

1.30 P.M.—The patient was visited for a few moments by his family, after which he was in a most excited condition. Hallucinations now appeared ; he thought that his father was by the bedside, and spoke to him. He appeared to be searching constantly for something, and looked anxiously in all directions. He thought that the solution of morphine was colored red. The special senses were in a state of exalted function, the patient was disturbed by the slightest sound, such as conversation in the adjoining rooms, even in whispers. He heard the voice of his father. He did not show agitation at the sight of bright objects, such as mirrors, watches, etc. He could still without difficulty place and retain his hands in a vessel filled with water, although all efforts to induce him to drink any liquid were fruitless. He could not swallow anything. He tried to take a part of an orange, but it was violently rejected.

The spasm and the salivation were increased. The patient was restless, uncovered himself, tried to sit upon the bed, etc. At times he was quiet for a few moments ; skin dry and burning ; pulse, 150.

Three o'clock.—Hallucinations of terror. The patient attempted to barricade the door of his room by means of the chairs. The spasm had become more violent, and he cried out in agony, and at times expectorated a moderate amount of viscid, frothy saliva. There was no tendency to bite. The intervals of quiet were shorter ; but at these times the entire body was relaxed. Temperature, 39.6° C. (103.3° F.) ; pupils punctiform.

The administration of chloral and injections of morphine now procured no relief ; but, on the contrary, furious delirium became rapidly more and more marked, so as to require the use of the camisole. The patient resisted the application of the camisole, saying that he had done nothing, and that the room might be locked, but that he would not submit to the jacket. With a great effort the camisole was applied, when he tore it in shreds, and seizing a slat from his bed, he crashed it through the window, and tried to escape. A stronger jacket was applied, and the patient was thus restrained.

Four o'clock.—The agitation was now terrific. The face had become cyanotic. The spasms were more violent, so that respiration was interrupted. The patient sweated profusely. Had passed no urine since morning. Pulse, bounding, 160. Rigidity of the neck and the limbs.

Five o'clock.—Collapse. Cessation of the cries, and cyanosis.

White, frothy saliva flowed from the mouth with each expiration. Respiration irregular. Pupils punctiform. Subjunctival ecchymosis. Corneal reflex almost absent.

Six o'clock.—Collapse more pronounced. Eyes largely opened ; pupils dilated ; corneal reflex absent ; corneæ dry. Profuse cold sweat. Respiration soft and still, but very irregular ; the contraction of the diaphragm was still marked, and caused the bed to shake at each inspiration. No alvine evacuation. Tympanites.

Seven o'clock.—Twenty-two respirations per minute ; irregular. Cyanosis more pronounced. White and abundant froth flowed over the face and neck. Pulse thready and tremulous, and could not be counted. Head, burning ; extremities, cold. Pupils very large. One hour later, dead.

Control Experiment.—Immediately after the autopsy (made fourteen hours after death), the pons, medulla, and cord were transmitted to M. Pasteur, with the history of the case. M. Roux made inoculations in rabbits, and the animals all died after an interval of fourteen days, with the typical symptoms of rabies, thus confirming the diagnosis.

It is important to distinguish rabies from other forms of tetanic diseases, or, in other words, from other forms of tetanus. The similarity between the rabic spasms and those due to other causes is so great that some authorities deny the existence of two diseases, and consider rabies to be one form of traumatic tetanus. Cases are recorded in which traumatic tetanus presented the specific symptoms of rabies, and were confounded with this disease. These doubtful cases are valuable as teaching that not all cases of this disease run an exactly similar course ; and that not all forms of the disorder are of service in explaining the pathology of the rabic process. The horror of liquids is not a common symptom of traumatic tetanus, nor is psychic disturbance a usual accompaniment of this form of tetanus.

The clinical history of rabies is often obscured or rendered difficult from the fact that the patient is inclined to deny the existence of a bite of inoculation, and the original wound is often completely healed at the time when the patient applies for treatment. Many cases of suspected rabies cannot be traced to the bite of an animal known to be diseased. Rabies is sometimes simulated by the symptoms of acute softening of the brain, or by those of acute meningitis ; but in these cases the most characteristic feature of rabies, the augmented irritability of the respiratory and of the reflex centres, either is not present at all, or is not a prominent symptom.

After death from rabies, the body is quickly distended by gas, which is formed in large quantities, and the post-mortem imbibition is usually strongly marked.

Clinical History.—The study of rabies must be considered to begin with the observation of the disease in the dog (rabies canina). There are two distinct varieties of the disease, the maniacal and the paralytic forms. The disease is marked by three stages: the prodromal, the irritative, and the paralytic. During the prodromal stage the animal is of variable temper, refuses his favorite food, passes quickly from excitement to depression and *vice versa*, swallows the most unusual substances, has generally a marked degree of sexual excitement, associated with a progressive, gradual weakening of the hinder extremities, trembling of the limbs, and a faltering gait.

The dog becomes unruly and obstinate, or sometimes timid and suspicious. There is often a marked secretion from the nasal passages, some embarrassment in swallowing, with a tendency toward vomiting. The original bite is generally quite sensitive at the time when the symptoms of the invasion of the disease begin to become evident. After a period varying from a few hours to three days, the symptoms belonging to the second stage are gradually developed and quickly become distinctly marked. The characteristic features of this stage consist in an evident tendency to roam, and to wander away from home. There is also at this time a marked disposition to bite, and there is an unmistakable change in the voice.

These symptoms are accompanied by undoubted indications of hallucinations of sight and hearing. The peculiarity of the voice consists in the prolongation of the initial bark into a protracted cry, the latter portion of which is raised in pitch to the octave, or nearly that, of the tone in which the cry commenced. The sound is more to be compared to a prolonged howl than to ordinary barking, but the intonation and pitch of the cry are unlike anything else in the way of canine sounds. There is usually at this time no hydrophobia in canine rabies. There is, indeed, marked inability to swallow either fluids or solids, the efforts to accomplish which often lead to vomiting. The loss of strength is therefore progressive and rapid. The mucous membrane of the mouth is often dry and fissured. Salivation is observed only in cases in which there is paralysis of the parts concerned in deglutition. The tongue, nose, and oftentimes the entire head are swollen, the conjunctivæ reddened, and there is usually photophobia. The respiration is generally hurried and difficult; there is frequently tenesmus, so that the passage of excrement is not only painful, but often impossible. The animal strains, and often the excreta are tinged with blood. The tenesmus is so frequently a symptom that some observers have considered that there is an intestinal lesion in the pathology of rabies.

A peculiar characteristic in the mad dog is the absence of the sense of pain—a red-hot poker will be grasped and held in the mouth. Dogs will bite themselves and still utter no cry. Periods of calm succeed these accessions of excitement, but during them the bite of the animal may still communicate the disease. Exhausted by the paroxysms, and the fighting and wandering, the dog will still continue on in its unsteady gait, with the tail between the legs, eyes wandering, the head rolling from side to side, and the mouth open with the tongue protruding.

Following the stage just described, and appearing as the intervals between the paroxysms of the disease become shorter, the paralytic stage supervenes. The hinder extremities become feeble, the voice hoarse, the respiration labored, and the heart's action accelerated. At times the convulsions appear early, and the animal generally expires after a longer or shorter period of coma, usually in from five to seven days from the onset of the disease.

Horses, cattle, and sheep, when affected by rabies, usually show no disposition to bite. Goats and swine are, as a rule, inclined to bite. Rabies is especially dangerous in cats and other carnivorous animals, on account of their greater ferocity. Domestic poultry is subject to rabies, and occasionally a tendency to bite is observed in these animals. True rabies is necessarily fatal in the present state of our scientific knowledge. Drugs and treatment of every kind, sort, and description, have been tried without avail (Mott).

Pathology.—Rabies is eminently an infectious disease, and is communicated from one animal organism to another by direct inoculation of the infective material. The pathology of rabies is not clear, and many observers have doubtless added to the existing confusion by recording the results of mistaken observations. The disease is eminently an acute and degenerative malady, and its special seat seems to be in the higher nervous structures. There can be no doubt that these delicate structures might suffer serious pathological changes, from the intensity of the disease, and undergo a more or less extensive process of acute softening, fatty degeneration, colloid degeneration, thrombosis, and other serious changes, from the presence of such an active febrile disturbance, with the added element of recurrent convulsions, even if rabies were not present. Many of the reported pathological appearances are unquestionably produced post mortem by the wounding of the softened and friable organs in making the autopsy. Benedikt, Hammond, Weler, and Putz have noticed changes of this character. In a case under the observation of the writer, in the Charité in Berlin, the autopsy was made by Professor Frerichs with his usual great care. The entire cerebro-spinal nervous system was examined, but no distinctive lesions were detected. When one considers the great delicacy of these organs, and the accidents to which they are exposed during the process of removal from the body, one can readily believe that many of the reported lesions, thought to be due to rabies, may have been mechanically produced at the autopsy. There is no disease in which the opportunities for mistaken pathological appearances are more abundant or more delusive than in rabies.

Rabies has practically been a disease of unknown character (pathologically) until within the latest years. The researches of the most celebrated observers have, however, led to the detection of an ever-increasing similarity between rabies and the class of diseases, also inoculable, which depend upon the presence of a definite organism in the body as the essential element of the disease.

The symptoms of rabies, in all cases, point to the infection of the system with the virus of the disease as the first source of the malady. The disease seems to depend upon the presence of a foreign element, partaking of the nature of the bacterial organism, or of a pathological ferment, which increases within the system and finally produces the explosion of the disease. From the nature of the phenomena it is evident that the seat of the active lesions is the nervous system, although all the tissues of the body are capable of communicating the disease.

The specific germ of rabies has not thus far been isolated, as have those of anthrax, tubercle, cholera, etc., nor have successful cultures of the infecting principle been as yet produced. The reported pathological appearances found in rabies are most various, and are often exaggerated by the results of accidental injury of the nervous structures from violence on the part of those making the autopsy. All observers, however, agree that there is evidence of molecular changes in the textures of the nervous tissues, chiefly of the nature of a granular degeneration of the nerve-elements, with the existence of granular deposits along the course of the smaller blood-vessels and lymph-channels. This material is so abundant as to occlude to a certain degree the calibre of the vascular channels, and to materially interfere with the nutrition of the nervous structures. The fact must not be forgotten that these changes, as well as many others, may, to a certain extent, be due to the great loss of liquids which the system has sustained; and it may also be in part accounted for by the violent convulsive movements which are so frequent and so distressing. The secretion of the saliva alone is sometimes enormous, and the other liquid secretions and excretions are also sometimes exaggerated during a part of the course of the disease, at the same time that the amount of fluid taken by the patient is greatly diminished. The nerves of the parts in which the original bite or inoculation occurred have been observed to present marked pathological ap-

pearances. The myeline is found in a diffluent condition, and in disconnected masses. The structure is softened, and the axis-cylinder is at times absent in many of the nerve-tubes. The same observation has been recorded in relation to the nerves arising from the medulla, the pneumogastric, the glosso-pharyngeal, and the hypoglossal; also the spinal accessory and the phrenic have been found to be the seat of ecchymosis and of localized apoplexies. Benedikt thinks the local lesions are sufficient to account for the clinical features of the disease. The digestive system is the seat of more or less pathological change, as might be expected, and there is often congestion of the liver and spleen.

PROGNOSIS.—The termination of rabies under any known form of treatment has been universally of a fatal character. Indeed, but few recognized diseases have so uniform and inevitable a tendency to a fatal issue, under all circumstances, as the dreaded malady of which we are now treating. Cases of the disease in which recovery has occurred are generally conceded to have been the subjects of mistaken diagnosis, or have been simply one of the simulating affections of which mention has already been made (Lyssa falsa seu nervosa).

Many methods of cure have been advanced in cases of rabies, and each recovery has been attributed to some new mode of treatment; but thus far no form of medication has proved to be of the slightest avail in the curative treatment of this dreadful malady. It would seem that any medical treatment should be directed to the reduction of the exalted susceptibility of the nervous system, and to the preservation of the strength of the patient. The administration of nervous sedatives or the employment of anæsthetics would seem to be indicated, together with most careful nursing, in the hope that the disease may run its course and at length subside.

Rabies simulates the class of self-limited diseases in many ways, both in its onset and in the character of its effects. As yet, however, there is no known method of prolonging the life of the patient in this disease. Professor Mott states that "true rabies is necessarily fatal in the present state of our scientific knowledge."

This seems the proper place to allude to the researches of M. Pasteur, of Paris, who for many years has labored in the department of experimental investigation in relation to infectious diseases, and has made many important discoveries in the domain of germ-pathology. He has succeeded in discovering the means of protective inoculation in several of the malignant diseases of plants as well as of animals. His researches on Anthrax, on the Phylloxera, on Rouget, etc., have been universally recognized.

The study of rabies by M. Pasteur has extended over a period of several years, and has been conducted with a degree of care and patience truly remarkable. He has found that the infective principle of rabies (which he calls a "virus," although the material of inoculation has not yet been discovered, either by culture or by any other method of procedure), when inoculated directly from the dog into animals of other species, is variously affected in the degree of its intensity, or, in other words, in its degree of virulency. Thus, when inoculated into the monkey, and propagated from one animal to another in a continuous series, the virus of canine rabies soon lost its virulent character and was no longer fatal to dogs on inoculation. If, however, the virus were propagated through a series of rabbits in the same manner, it was found that the virulency of the rabic poison was rapidly increased in intensity, so that the virus taken from a successive culture through a series of rabbits was found to kill dogs much more quickly than the original virus taken directly from rabic dogs (rage de la rue, Pasteur), in whom the poisonous principle seems to be possessed of a certain definite degree of virulency midway between that of the same poison when passed through the system of the monkey and that obtained when it is passed through rabbits (see "Comptes Rendus").

The specific element of rabies is not yet definitely determined, though Professor Pol, of Geneva, has announced that he has discovered a definite organism which can be isolated and propagated by successive cultures, and which possesses the property of inducing the rabic disease in dogs or other animals. This assertion is not yet verified by the confirmation of other observers, but there is reason to hope that the infective material may yet be isolated, and may be proved to belong to the same general class of organisms as that of anthrax, erysipelas, diphtheria, cholera, etc. Pasteur has determined that the seat of the rabic disease is the nervous system, especially the brain and spinal cord. By suspension of the brain or spinal cord in an elevated temperature, the virulence of the poison was found to be progressively diminished, so that by this means an attenuated or enfeebled virus may be obtained. The diminution of the rabic virulency was found to be regular and uniform in cords treated in this way, so that the degree of attenuation can be accurately estimated, and a virus of any desired degree of activity may thus be secured, from that possessing fatal power to one which provokes only a moderate amount of febrile or inflammatory reaction.

The next step was to test the value of protective inoculation by these attenuated forms of virus. This was first carried out on animals, and later, after numerous trials, upon the human subject (Joseph Meister). It was found that the animal system became easily tolerant of the rabic virus in a state of attenuation, and that more powerful forms of virus might then be inoculated without danger, until the original virus of the dog (rage de la rue), as taken directly from the rabid animal, might be injected directly into the tissues of the animal, on which the attenuations in increasing strength had been successfully employed, without producing the slightest symptoms of danger. Here, then, it was proved that the animals thus protected were no longer susceptible to the immediate effects of rabies, even when bitten by dogs which were unquestionably the subjects of this disease; at the same time that other unprotected animals, similarly bitten, invariably died of typical rabies.

There seems reason to believe that the inoculation with rabic virus, as thus practised, may protect the individual from the rabic disease, though the period of time through which the protection lasts is not determined; and it is yet too early in the history of this mode of prophylactic treatment to allow a settled opinion upon a point of such stupendous importance.

As far as a long series of experiments on animals can determine (see "Comptes Rendus"), the protection, for the time at least, seems to be all that can be desired. Rabid dogs have been made to bite a series of animals which had been protected by inoculation, and also a series of animals which were not so protected; the unprotected animals, without a solitary exception, died of rabies in all its terrible intensity, while not one of the protected animals was in the least affected.

The value of a complete "control" in experimental pathology, as a means of confirmation, cannot be more clearly demonstrated than in the present course of studies. In all the inoculations of the human subject there has been a control inoculation of a rabbit with the same material as was inoculated into the person.

The material used for inoculation is a portion of the spinal cord of a rabbit, which has been simply triturated with a small quantity of pure water or other bland and sterilized fluid, so as to reduce the substance of the cord to a more or less fluid condition. The matter for inoculation is not subjected to any further treatment, but the portion of water holding in suspension the bruised and finely divided substance of the cord is injected directly into the tissues of the patient. With each injection the tolerance of the system to the rabic virus is increased, and at each successive injection a cord may be used which is of a greater degree of virulency than those which have been previously employed, until, at the expiration of a certain number of days, the system of the inoculated individual is not susceptible to the poison of the most virulent form of rabies in the dog or in the rabbit.*

* During December, 1885, several children were bitten by the same supposed rabid dog, in the streets of Newark, N. J., United States. The actual condition of the suspected dog was not satisfactorily ascertained,

PROPHYLAXIS.—This may be divided into two sections —*general* and *protective* prophylaxis.

I. *General Prophylaxis.*—Among the most important elements of purely prophylactic treatment of rabies must be classed that which pertains to the management of dogs in large towns, which are not the subjects of rabic disease. There is probably no measure of public hygiene which is followed by more certain and positive results than those which have been attained by the compulsory muzzling of all dogs which are allowed to be at large, and the prompt destruction of all dogs found in the streets without a muzzle. In the city of Berlin, where this ordinance has been in force for some years, there has not been a case of rabies for many years.

There can be no doubt that this mode of treatment of metropolitan dogs would be the most practical, and at the same time the least objectionable method of securing the public against the ravages of the rabic disease, so far, at least, as city dogs are concerned. It would not, perhaps, affect dogs in rural neighborhoods, nor would it materially diminish the dangers from rabies derived from other animals, such as wolves, foxes, skunks, etc., as the rabic disease is rarely communicated to them from dogs, but more frequently they are the source of infection of dogs or other domestic animals, and at the same time they are the cause of the disease in not a few instances in the human subject.

The wearing of a muzzle is not a hardship for the dog, as it can be made of metal, and may be so constructed as to be at the same time both light and strong, and in no material way diminish the comfort or impede the movements of the animal, except in the one feature of restraining him in any attempt to bite either men or other animals. The muzzle might be easily removed, and during all that portion of the day in which the dog is kept on the premises of the owner, he might go about without being muzzled ; but when at large the muzzle could be easily slipped over the animal's head, and thus the danger of his biting anybody be removed.

Dogs do not, as a rule, find the muzzle any inconvenience, and appear quite as cheerful when muzzled as when unmuzzled. Respiration is not impeded, nor are the motions of the dog in any way interfered with. The only effect of a proper muzzle is to prevent the dog from seizing any article, or taking a grip in any effective way with the teeth.

Another element of prophylactic treatment is the important one of the impounding of all suspected dogs, and their retention in some secure place, where careful observations may be made and their condition be satisfactorily ascertained. If rabies be present in a suspected dog, the disease will surely manifest itself in a few hours or days, and all doubts in relation to the existence of the disease will be dispelled. No suspected dog should be killed until such observations have been made, unless experimental inoculations are carried out by means of the injection of portions of the nervous system, as a control of his condition. The foolish idea that immediate destruction of the suspected dog is a source of protection to any person who may have been bitten by him is still extant, and often prevents investigation of the actual condition of the dog, by which, in most cases, all fears from the bite might be effectually laid at rest.

II. *Protective Prophylaxis.*—The extensive researches of M. Pasteur into the pathology of rabies have developed the important theory, which has now become an established belief, that the inoculation of the system with the virus of this disease is the means of securing immunity from the attack of this most frightful malady, after the introduction of the infective material into the body from the bite of a rabid animal.

The present state of this most important question is well set forth in an article contained in the *Annales d'Hygiène Publique*, December, 1886, which is here reproduced almost *in toto:* "It is now one year (October 26, 1886) since Pasteur made the announcement of the prophylaxis against rabies after a bite from a rabid animal. A large number of experiments upon dogs warranted that the attempt at protection be extended to the human subject. This was at length done, and up to March 1st 350 persons, who had been bitten by dogs known to be the victims of rabies, had been treated by Dr. Grancher in the laboratories of Pasteur.

"At this date, October 31, 1886, the number of persons who have submitted to the protective inoculations in Paris is 2,490. The treatment has been absolutely uniform for the great majority of those bitten, notwithstanding the diversity of age, sex, the number of wounds, the seat of the lacerations, their depth in the tissues, or the length of time which has elapsed since the reception of the injuries until protective treatment was instituted. The period of treatment extended over ten days. Each day the person treated received one injection of the spinal cord of a rabbit, commencing with a cord which had been dessicated for fourteen days, and finishing with one of five days.

"The entire number of French patients, being those dwelling in France, or French persons coming from Algeria, who have been inoculated during the last year is 1,700, and we can properly limit our observation to the description of the treatment of this quite considerable number of French-speaking people, and may form an opinion of the effect of the inoculation by a study of these cases.

"Among these 1,700 patients there were ten in whom the effects of the inoculations were not productive of immunity from the occurrence of rabies. These were the following cases: Those of the children Lagut, Peytel, Clédière, Moulis, Astier, Videau ; the women Leduc (seventy years of age), Marius, Bouvier (thirty years of age), Magneron (eighteen years of age). Two cases, those of Louise Pelletier and Moermann, are not included in this category, on account of their very late arrival at the laboratory, by reason of which the efficiency of the protective inoculations may have been modified, or the disease may have been already developed before their appearance in Paris. One case of death in each 170 persons bitten is, then, the result of this method, for France and Algeria, during the first year of its application as a protective against rabies. Taken as a whole these figures demonstrate the efficacy of this method, which is equally proved by the relatively large number of deaths among those bitten but who were not vaccinated. One may feel certain that during the year 1885-86, there were comparatively few persons bitten by mad dogs in France who did not apply for protection at the laboratory of l'École Normale. Even in this small minority there were, to my personal knowledge, 17 cases of death from rabies." (In a note, M. Pasteur gives exact reference to each of these cases, none of whom was inoculated for protection.)

"During the last five years sixty persons have died from rabies in the hospitals of Paris. That is an average of twelve per year. No year of the series was exempt from a certain number of deaths. During the last year of the series, the number of deaths was twenty-one. Now, since November 1, 1885, which was the date of the introduction of protective inoculation for the human subject into practice, in my laboratory, there have been in all the hospitals in Paris but two cases of death from rabies, neither of whom had received protective inoculation

as the animal was immediately killed. The children were sent at once to Paris by public subscription, and there, immediately upon their arrival, received the protective inoculations at the laboratory of M. Pasteur. The virus was prepared from the spinal cords of rabid animals in the manner above described. The first inoculations were with virus which had been much attenuated. With each succeeding inoculation the virulent quality of the inoculation was increased, until the material used was the virus taken from an animal newly dead from rabies. As soon as this limit was reached the children returned to the United States, where they have since that time been under careful observation by competent medical men, and up to the time of the present writing (twelve months) they seem to be free from any tendency to the disease.

The above reported cases are the first instances in which the protective vaccination has thus far been the subject of observation in the United States, and are of great interest on that account, though there is some uncertainty as to their absolute value, owing to the absence of positive knowledge as to the condition of the dog by which these children were bitten. Nine other dogs were said to have been bitten by this dog on the same day that the children were bitten. These nine dogs were all secured and impounded, where they were kept under observation during the period of three months. At the end of this time none of these dogs had showed symptoms of rabies, and they were all set at liberty.

(Raffin, at Hôtel-Dieu, and Riffandi, at Hospice Beaujon), and a third who had been inoculated, but not by the repeated intensive method, of which I will speak later (Clerjot, at Hôpital Tenon).

"It will be observed that the larger number of those who have succumbed to the disease, in spite of the treatment, are children, and that they were bitten in or about the face. These children received only the first simple form of treatment. I have since become convinced that this form of treatment, particularly in cases in which the wounds were of this character, runs the risk of being insufficient. Unfortunately, this conviction was reached only gradually, and after long study, which was necessary to establish the fact of an exceptional duration of the period of incubation in certain cases of rabies. The history of the disease among the Russian patients from Smolensk was the first proof of this fact which had come to our notice. From these cases we learned that there is a vast difference in the results of infection with the rabic virus, whether the source of infection be a mad dog or a mad wolf.

"From reliable sources the following statistics have been collected in relation to the bite of rabid wolves. These are published for the first time.

"1. On February 27, 1796, eight residents of Saint-Jullien de Civry, in Bourgogne, were bitten by a mad wolf. One died on the same day from the severity of his wounds. The other seven died after a period of incubation extending from seventeen to sixty-eight days.

"2. December 26, 1806, nine persons were bitten by a mad wolf in the vicinity of Bourg. Of these eight died of rabies.

"3. On October 16, 1812, nineteen persons were bitten by a mad wolf in the town of Bar-sur-Ornain. All of these patients were at once treated by Drs. Champion and Moreau, who washed the wounds and cauterized them by means of nitrate of antimony. Eleven of those bitten died of rabies after a period of incubation of seven to seventy days.

"4. On February 23, 1849, a shepherd in Darbois, named Dumont, sixty-four years of age, was bitten by a mad wolf. He died, after a period of incubation of thirty-two days, of typical rabies.

"5. On January 7, 1866, three inhabitants of the three neighboring hamlets of Nant, Alques, and Saint-Jean du Bruel were bitten by a mad wolf. All three died of rabies on the twenty-second, twenty-third, and thirty-eighth days.

"6. On October 5, 1874, two men were bitten in the village of Rochette by a mad wolf, who had just seized a little girl and had torn her in pieces. After twenty-five and thirty days, respectively, the two men were seized with the disease, and died of rabies. The child died on the day of the attack, from her injuries.

"7. In a letter of March 26th, Dr. Nipce, of Eaux de Allevard, communicated to Professor Vulpian four cases of bites from a mad wolf, occurring in the year 1822. The four persons died of rabies, after a period of incubation of from nine to nineteen days.

"8. On May 11 and 12, 1811, a mad wolf, in the vicinity of Avallon, bit several persons and many animals. All the persons bitten died of rabies. The dates of death in the different cases, as taken from the records of the hospital, vary from the twenty-fourth to the thirty-first day after inoculation.

"From a comparison of these reports we arrive at the ratio of 82 deaths in 100 cases of inoculation from rabid wolves. In six of these eight reports there were as many deaths as there were persons bitten, hence the ratio would be in these cases one hundred per cent. of fatal cases.

"The above reports prove that, first, the incubation of human rabies after the bite of a rabid wolf, is often very short, much shorter than is the case after rabies from the bite of a mad dog.

"Second, that the mortality in consequence of the bite of a mad wolf is much greater in comparison than is the case after the bite of a mad dog. If we apply these facts to the cases of the nineteen Russians from Smolensk, whose treatment is finished, and of whom sixteen have returned to Russia, we could have reckoned not upon three deaths from rabies, but upon fifteen out of sixteen! In Russia it is universally believed that no one who has been bitten by a mad wolf can escape death from rabies.

"When we saw three of those nineteen patients from Smolensk die from rabies while under our observation—the first being in the course of the former simple treatment, and the two others having already finished their treatment some days before—we were much troubled. Would the sixteen others also become victims of rabies? Was the method unavailing against rabies derived from the wolf? We then recalled the fact that all the dogs which had been vaccinated with success had received, as the last preservative inoculation, a preparation from a virulent cord removed the same day, and that the first person to undergo vaccination, Joseph Meister, had finished the treatment by a cord which was removed the evening previous to being used. We then at once made a second and a third course of inoculations upon the sixteen Russians who still remained alive, increasing the intensity of the inoculations until the cords of the fourth, third, and second day were reached. It is very probable that to these repeated inoculations is to be attributed the cure of these sixteen Russians. A despatch received on the day of this report from the Mayor of Beloi, announces that these patients are all in the best of health.

"Encouraged by these results, and by the new facts obtained thereby, a new method of treatment has been adopted, by making the inoculations more rapidly, and of more active quality, in all cases of wounds of the face, or in cases of deep wounds and multiple lacerations upon other uncovered parts. Three complete treatments are therefore made in the space of ten days, and in each treatment the last cord used is one of most virulent intensity."

The opinion of the profession upon the discoveries of Pasteur is very clearly set forth in an address by Dr. T. W. Hime, in the London *Lancet*, December 11, 1886.

Dr. Hime says: "The success of Pasteur's treatment has been brilliantly demonstrated by statistics as well as by experiments. That the disease in the rabbit from which Pasteur obtained his material for human inoculation was true rabies is indubitable. Nerve-matter taken from such a rabbit and inoculated in a dog intracranially, the only certain method, invariably produces true rabies. If nerve-matter be taken from a human being dead from an attack of canine rabies, and be inoculated in a rabbit, a guinea-pig, a dog, all three will take rabies and die. The dog will have rabies according to his kind, with symptoms either of the dumb or of the furious kind. The guinea-pig will exhibit very characteristic symptoms, and the rabbit will develop symptoms peculiar to his kind, such as for convenience may be called the 'Pasteuran disease,' but an interesting and important fact may be borne in mind. The virus used for the experiment, being canine virus, which has passed once through the human subject, will retain certain canine peculiarities as to period of incubation, date of death, etc. If, instead of human nerve-tissues from persons who have died from canine rabies, we employ nerve-matter direct from a dog which has died from rabies, for inoculation, the animal will be similarly affected, and the disease produced in the rabbit cannot be distinguished from that caused by inoculation with nerve-matter taken from a human being who has died from rabies after inoculation with canine rabies.

"If, again, nerve-matter be used taken from one of the rabbits employed by Pasteur for protective inoculation, the same result will be obtained, with this difference—the course of the disease in the various animals will be shortened. Pasteur uses for his protective inoculations virus which, originating in ordinary canine rabies, has been passed directly from rabbit to rabbit some hundreds of series. The result is that the virus has become intensified, and kills more rapidly than the original canine virus. It was actually alleged at one time that the deaths following Pasteur's inoculations were due to them. This was triumphantly disproved by the experimental demon-

stration that the virus in the disease was canine virus (and was due to the original bite), and not rabbit virus inoculated by Pasteur for protection. The opposite result is obtained if the virus be passed from monkey to monkey through a long series; the virus becomes weaker and weaker. But no doubt, just as the virus of anthrax, or fowl cholera, which has been modified by cultivation, could be brought back to its primitive virulence, so the weakened rabic virus of the ape and the intensified rabic virus of the rabbit could be brought back to the original degree of virulence. If Pasteuran virus be passed through the dog once, and then be inoculated on a rabbit, it will be found not to have resumed canine characteristics by passing once through the dog. But more frequent passages through the dog will probably restore its primitive characteristics. The symptoms are very special in the rabbit inoculated with Pasteuran virus; the length of the incubative period (five to six days), and the date of death (nine to ten days), are more invariable than in any other known disease of man or animals. Further, the symptoms are very characteristic and invariable, notably the slightness of the general symptoms, even after paralysis has become marked. The temperature is also very interesting, and markedly different from that found after intracranial injection with other materials than the Pasteuran virus or rabic virus from some other source. The following is a characteristic chart of the temperature of a rabbit which died of Pasteuran rabies: First day, 102.6°; second day, 103.0°; third day, 102.8°; fourth day, 103.0°; fifth day, 104.2°; sixth day, 105.6°; seventh day, 105.8°; eighth day, 106.4°; ninth day, 104.1°; tenth day, 97.0°; eleventh day, 86.0°.

"The febrile stage may be shorter, and the fall more gradual, but the latter is always great. The elevation is not always so great as in this example, but the rhythm is characteristic, and the temperature usually gives indication before the actual symptoms appear. The course of the temperature in the rabid dog is similar. At first there is no change; then the temperature rises gradually and may reach 105.0° or 106.0°. The period of acme lasts one or two days, and is succeeded by a rapid fall to about 84.0°, when death ensues. The fact that the disease is always and invariably transmissible by inoculation is of great importance as regards its pathology, and as distinguishing it from other diseases. With regard to post-mortem appearances, there is nothing pathognomonic in the Pasteuran rabbit, any more than in the dog, or in the human subject dead from rabies. All the organs appear free from disease; some more or less hyperæmic; and sometimes hæmorrhages are found; the brain is slightly hyperæmic as a rule, the heart contracted, and the bladder generally full. The stomach almost invariably contains food; the cæcum is commonly full; the remainder of the intestine generally contains but little; the small intestine nothing. This absence of morbid conditions is remarkable, and is certainly not found after death from injury to the brain after operation, nor after death from intracranial injection of other materials—putrid material, etc. In this case, pus would be found within the cranium, and other evidence of purulent absorption would be detected.

"Intracranial injection of sterilized bouillon will not produce the symptoms of Pasteuran disease, nor any other morbid symptoms, and rabbits so injected will not die if skilfully operated upon. Rabbits inoculated according to Pasteur's methods, with sterilized bouillon rubbed up with putrid meat, will die, but with symptoms entirely different from those of Pasteuran disease, and without the characteristic paralysis. But still more noteworthy is the fact that the disease produced by injections of putrid material is not transmissible. If fresh nerve-matter be taken from a rabbit which has died in consequence of disease produced by intracranial injection of putrid matter, and be injected intracranially, according to Pasteur's method, on another rabbit, the latter will not die, and will have no specific disease whatever, nor marked symptoms of any kind if skilfully operated upon. But the Pasteuran disease is always transmissible by intracranial injection. Nerve-matter from dogs which have been suspected of rabies, and have died or been killed in consequence, has been frequently injected intracranially on rabbits as a diagnostic measure; if the dogs were rabid the Pasteuran disease will be developed in the rabbits. If not, the rabbits will survive, without showing any symptoms of this disease or any other disease. That this crucial method of diagnosis exists is due to Pasteur. In fine, the following results are established: the virus used by Pasteur for protective inoculation originated in the rabid dog, and is the virus of rabies. Pasteur has published results showing that the material used for his latest protective inoculations on man, caused rabies in animals which were unprotected. If virus be taken from a rabid dog, and be passed through a series of rabbits, it will produce the same disease as is developed in the rabbits from which Pasteur takes his matter for protective inoculations. If the virus of such inoculations be inoculated back into the dog or other susceptible animal, it will produce true rabies in them, and if then passed back to the rabbit it will produce the same symptoms *ad infinitum*.

"Human rabies, if inoculated on the rabbit, will produce the same symptoms, with such variations as are due to its origin in the dog, cat, etc. These variations are exhibited chiefly in the period of incubation, and the period elapsing before death, the disease invariably terminating fatally. No other known disease produces the same results, nor can the symptoms be caused either by surgical brain-lesion or the intracranial injection of inert material, such as sterilized bouillon, or with putrid material. The Pasteuran disease is specific, and very distinctly characterized by its course and symptoms, which are different from those of any other disease; it invariably ends fatally, and is indefinitely transmissible by inoculation from animal to animal. The protection afforded to dogs by Pasteur is proved beyond doubt or question, and analogy suggests that the same method is applicable to man. Dogs can be protected either by inoculation before infection, or after this has occurred. Further, they have been protected against the action of the rabbit virus, which is much more active than ordinary canine virus. The reality of this protection establishes the truth of Pasteur's principle. His practice may be capable of improvement; but he has already effected a great deal in a short time. It has been objected that the inoculated prophylactic virus is inert, because the patient shows no specific reaction. It is almost always the case that there is a slight though decided reaction. Pasteur has established a prophylactic treatment against rabies, one of the most formidable, and hitherto intractable, diseases. He has thus crowned a glorious career of research directed to the benefit of man by a most notable discovery, primarily salutary to man himself."

The statements of Dr. Hime are corroborated by the report of Dr. Grancher upon the cases treated by Pasteur's method in the laboratories of the institute, which is as follows (up to April 22, 1886):

"The cases were divided into three classes. The first class included those bitten by dogs proved to be mad by the inoculation of rabies, or subsequent development of rabies in animals bitten by them. These amounted to 96 cases, and contained one death. The second class comprised patients bitten by dogs certified to be rabid by the veterinary practitioners of the locality, and numbered 644 cases, and two deaths. The third class contained those bitten by dogs who had run off and had not been seen again, 232 cases, with no deaths.

"In the first two classes, 740 cases, with three deaths, not quite one-half of one per cent. of those bitten; while the ordinary statistics of light cases given by M. DeBlanc, Veterinary Surgeon of the city of Paris, gives sixteen per cent. as the number of deaths. Dr. Brouardel has calculated that no less than eighty per cent. of those bitten by rabid dogs on exposed parts of the body die. In the 84 cases of wolf-bite, not included in the above, 7 died; ordinarily sixty-six per cent. of those bitten by rabid wolves die, and here the percentage is fourteen."

Dr. H. C. Ernst, in a recent paper (*American Journal of the Medical Sciences*, April, 1887), describes a series of

experiments performed in the Bacterial Laboratory of Harvard University, from which he deduces the following propositions:

First, is there a specific virus in the brains and cords of rabbits inoculated with Pasteur's materials, and after his methods?

Second, does the treatment by drying, proposed by him, modify the strength of this virus? and

Third, does injection with such "modified virus" produce immunity against inoculation (or bite) with virus of full strength?

The essay closes with the following:—The conclusions which may be drawn from the work here recorded seem to be as follows:

1. There exists in the cords and brains of animals inoculated in Pasteur's laboratory a specific virus, capable of the production of similar symptoms through a long series of animals.

2. These symptoms are produced with absolute certainty when the method of inoculation is by trephining the skull, and in injection under the dura mater; with less certainty when the inoculation is by subcutaneous injection.

3. The strength of this virus is lessened when the cords containing it are removed from the animals and placed in a dry atmosphere, at an even temperature.

4. The symptoms produced by the inoculation of this virus appear only after a certain period of incubation, distinctly shorter when the inoculation has been done by trephining than when done by subcutaneous injection.

5. The injection of the virus, modified in strength by drying, and in the manner prescribed by Pasteur, exerts a very marked protective influence against an inoculation with virus of full strength.

6. A very moderate degree of heat destroys the power of the virus entirely, while prolonged freezing does not injure it.

TREATMENT.—In the actual care of cases of rabies, in any form, the treatment is essentially divided into two distinct forms: the prophylactic and the clinical.

The first consists in the destruction or the confinement of all suspected animals, and the isolation and careful and lengthened observation of all animals which have shown indications of rabies, and which have bitten other animals or have attacked men. The disease is usually developed in the dog within a certain tolerably definite period, and if the imprisoned animal demonstrates no indications of the disease within these limits, it is fair to assume that rabies was not communicated by the same dog in biting other animals or men.

The second part of the prophylactic treatment of this disease consists in the early and proper care of the wounds caused by the bite of animals thought to be rabid. All such wounds should be promptly cauterized by means of the ferrum candens, nitrate of silver, caustic potash, or by some other efficient means.

After cauterization the wound may be completely excised.

It is considered a wise procedure to maintain suppuration in the wound for a long time. The safety of the patient is increased in proportion to the earliness of the treatment of the wound. Sucking of the wound is a usual procedure, but it may be a dangerous measure on account of unnoticed injuries of the mucous membrane of the lips or mouth, by which fatal infection of the system might occur. This mode of treatment requires an unusual amount of courage and self-sacrifice.

The therapeutical measures in this disorder relate to the treatment of the disease after it is actually and unmistakably developed. In view of the fact that cases of this disease are uniformly and inevitably fatal, and that no known method of treatment is able to prevent the lethal result, there is little to be hoped from any mode of procedure.*

It is important that the care of patients with rabies should be entrusted to responsible and skilful nurses, in order to avoid the employment of force in restraint, by which the patients might be injured, or which might unnecessarily increase the excitement and anxiety of the patients. The subject with rabies (human) is not dangerous to those about him, nor is he inclined to injure himself.*

All appearance of forcible restraint or of fear should be removed, and the patient should be comforted as much as possible.

The terrors of this fearful malady are greatly intensified by the unnecessary fear, and often by the cruelty, of those about the patient.

We know of no method of favorably affecting rabies in the way of treatment when the disease has once appeared. We do not even know how to ameliorate the agonies of the severer symptoms.†

Among the measures which may be adopted are certain influences addressed to the mental and moral condition of the patient, by which some degree of relief may often be secured. Thus drinks may be taken through an opaque tube, or from a dark-colored vessel, so that the fluid may not be seen by the patient.‡

Much relief may be secured in some cases from the subcutaneous employment of morphine; the application of electricity has also at times seemed to be of service.

The great question, whether there is any other method of treatment of rabies than that of protective inoculation by means of the attenuated virus, by which the disease may be controlled when infection has occurred from the bite of a rabid animal, is one of the undecided problems of our science. From the stupendous strides which have been made in the advancement of therapeutical knowledge, particularly in relation to the products and effects of the large class of synthetic compounds, there is reason to hope that we may at length acquire the means of restraining infectious diseases, due to the invasion of the system by pathogenic bacterial forms, or to other infective agencies, if such other agents of infection exist. With the attainment of this increased ability to combat the development of the specific germs, we shall possess the means of limiting and controlling the ravages of epidemic diseases. The scope and importance of such a tremendous addition to our therapeutical resources is

* In connection with the above statement should be considered the lengthy description, on a previous page, in relation to the treatment of rabies by protective inoculation or vaccination, as devised and practically carried out, in relation both to the lower animals and to man himself, by M. Pasteur, of Paris. The value of this new method of treatment is not yet fully and satisfactorily demonstrated in relation to the human subject, and therefore it cannot be said to have yet actually taken the position claimed for it as a therapeutical and prophylactic measure, though there are strong reasons for the hope that it may prove to be a safe and sure preventive of the rabic disease.

* Benedikt mentions a case in which a dog-fancier was attacked, after many years, by rabies, following a new and recent bite by a dog, and on experiencing the first symptoms of the disease he hanged himself; but the tendency to self-injury is small in this disease.

† Kostyleff reports a case of rabies treated by inhalations of oxygen. The patient was a railway guard, sixty-three years of age, and intemperate, who had been bitten by a suspicious dog about four months before his admission. The symptoms of rabies consisted of an extraordinary sexual excitement, malaise, loss of appetite, and thirst. Three days later he was brought to the hospital. There was then hydrophobia and pain in the throat. Respiratory and pharyngeal spasm was frequent, and there was frothy expectoration mixed with blood. The patient was in a state of intense general excitement, with delirium of persecution. The effect of the inhalations of oxygen was most pleasing. After the first few inhalations the spasm entirely ceased, the expectoration was diminished, the cyanotic lips became rosy, the patient passed into a calmer condition, and could eat, drink, and smoke. After one and a half hour's sleep at night there was a return of the spasm with dyspnœa, which was again cut short by the oxygen. After an enema of chloral he again slept several hours, and then he was able to take two or three glasses of milk. On the following day he was able to drink, but soon after this time the delirium returned and he became gradually exhausted, and died on the fourth day. Kostyleff therefore thinks oxygen to be markedly palliative, but not curative.

‡ A man was admitted into the Massachusetts General Hospital in September, 1878, who had been bitten, as he claimed, by a rabbit, and had developed symptoms of rabies. The patient had no suspicion of the nature of his disease, and was not informed of the character of the malady while in the hospital, and died without knowing that he was affected with rabies. The attempt was made in this case to introduce fluids by means of opaque tubes, and by using darkened vessels, but without avail. The patient would at once experience the most frightful convulsions if his fingers were dipped into any fluid, even if he could neither see nor hear the liquid. The patient's condition gradually became more and more excitable, and he passed into a state of frenzy, in which he made his escape from the hospital, and was with difficulty retaken. He was brought again to bed, and died a short time afterward from exhaustion.

too vast and far-reaching for our present conception. The attainment of the result thus hinted at is no chimera, but is a warrantable expectation.

As a contribution to the possible therapeutics of rabies may be mentioned a case occurring in the practice of Dr. De Capua, of Naples, in which a patient, suffering from undoubted rabic symptoms following the bite of a mad dog, was treated by subcutaneous injection of mercuric bichloride, together with atropine. The case is reported in brief in the London *Lancet*, September 18, 1886. The rabic symptoms amended slowly, and the mental phenomena at the same time subsided in a gradual manner. The delirium assumed three distinct forms, and ended with a form of mental disturbance related to the occupation of the patient as a farmer; this soon abated, when complete physical and mental recovery took place.

Jagell, *Revue Scientifique*, August 21, 1886, quoted in *Medical Record*, January 1, 1887, treated eighty-eight cases resulting from the bites of rabic wolves and dogs, and all were cured by infusion of spiræa filipendula; twenty-six of these cases having been found already in the first stage of hydrophobia when treatment was commenced.

NOTE.—Since the above article was written, the protective inoculation, in cases of threatened rabies from the bite of a rabid animal, has been made the subject of unceasing study and experimental research by able men in every country. The general opinion has been that inoculation in the way advocated by Pasteur is not only an absolute protection to the patient against the outbreak of the rabic disease, but that it is itself entirely free from serious effects upon the inoculated person. For an interesting account of Pasteur's method and its results, as seen by Dr. Ullmann, of Vienna, see *Wiener Allg. Med. Zeitung*, 1886, No. 21. Dr. Ullmann allowed himself, as did also four other physicians, to be inoculated with the rabic virus. All remained well, and with the exception of moderate constitutional disturbance, experienced no deleterious effects from this courageous experiment.

For an exhaustive treatise upon this subject, with numerous references, see article on "Hydrophobia," by Bollinger, in "Ziemssen's Cyclopædia of the Practice of Medicine," American translation, vol. iii., p. 432 *et seq.*; also Pepper's "System of Medicine," vol. i., p. 886.

Albert N. Blodgett.

RAGAZ-PFÄFERS, called also Pfäfers-Ragaz, is a spa in Canton St. Gallen, Switzerland. There are really two establishments, but both receive their water from the same spring. Pfäfers is the higher (2,200 feet above sea-level) and Ragaz lies below, at an elevation of 1,700 feet. The climate is less raw and changeable in Ragaz, though in neither place is it very warm; by reason of their situation in the valley these stations enjoy the direct sunlight for only about six hours out of the twenty-four. The following is the composition of the water, according to the analysis of Planta.

One litre contains:

	Grammes.
Lithium chloride	0.002
Sodium chloride	0.493
Sodium sulphate	0.329
Calcium sulphate	0.075
Sodium borate	0.004
Sodium carbonate	0.061
Magnesium carbonate	0.531
Calcium carbonate	1.306
Strontium carbonate	0.015
Barytum carbonate	0.006
Ferrous carbonate	0.017
Aluminium phosphate	0.009
Silicic acid	0.141
Total	2.989

There are also traces of iodine, bromine, rubidium, cæsium, and thallium. The temperature of the water at Pfäfers is 99.5° F., but by the time it has reached Ragaz in the pipe-line conduit, it has been cooled to about 95.5° F. The waters are taken internally and in the form of baths, douches, etc. They are recommended chiefly in the treatment of excited nervous conditions, and of chronic rheumatism and gout. The season in Ragaz extends from the beginning of May to the end of October; in Pfäfers it is about two months shorter. In addition to the use of the thermal waters, there are facilities for the "whey" and "grape" cures. *T. L. S.*

RAILWAY MEDICAL SERVICE. In the infancy of American railroads, while they were few, short, and nowhere distant from centres of population, it could not have been supposed that the companies would derive any advantage from an organized medical department; nor is it likely that such a want was then anticipated, any more than an occasion for undertaking the business of mining, manufacturing, or the extensive planting of forest trees. But, as lines lengthened and business increased, occasions for surgical relief to passengers and employés multiplied, and the advantage of definite and permanent engagements with medical men became apparent.

It is evident that a strong corporation, well organized for a particular purpose, has facilities for undertaking new functions; and medical relief to employés, when they became numerous, would seem as natural a want as in a military establishment. But the actual outgrowth of railway medical service in Great Britain and the United States has been governed by the apparent necessities of companies, to obviate the greater expense of employing medical men only when their services were indispensable, and at their own prices. In France and other countries of continental Europe, where railroads have always been more or less under direct governmental control, and where a paternal government assumes complete supervision of the conduct of its subjects, a well-organized medical department has long existed on the more important roads.

The first, and for some time the only, occasions for the employment of medical men by railway companies were in a surgical capacity, for the relief of those injured in accidents, when it might be presumed that the companies would be held legally responsible for consequences. A service once organized for this purpose could be made available, without much additional expense, for the relief of employés, and even of their families, in ordinary sickness. The physical examination of employés followed later, and, last of all, hygienic measures for the prevention of disease. These come latest, not because of inferior importance, but because they are the highest development in the gradual evolution of medical science.

The medical service of some of the principal railways of France and Italy is the most elaborate in the world, and will properly serve as a model for general imitation, as it has already on the continent of Europe, and to some extent in British India, in Australia, and by a few companies in the United States. The medical department of the Paris, Lyons & Mediterranean Railroad has its headquarters at Paris, and is administered by a physician-in-chief and a number of district physicians, who are practitioners residing at convenient distances along the lines. All receive fixed salaries, and their duties are defined as follows:

The district physicians are required:

1. To attend gratuitously upon sick and injured employés, and all other persons accidentally injured upon the lines or in the premises of the company.

2. To ascertain and certify the general health and degree of corporeal fitness of applicants for the various branches of service, after careful physical examination.

3. To answer all calls for attendance in case of accidents upon the lines and in the establishments of the company.

4. To advise the directory in questions of hygiene and in the settlement of damages for personal injuries.

5. To inspect monthly, as far as possible, all establishments whose *personnel* is entrusted to their care, in order to certify their sanitary condition, and to inspect the relief-chests, medical stores, and apparatus of the medical service.

6. To report monthly to the physician-in-chief the condition of the sick and wounded, and the results of the inspections, adding thereto any necessary observations and requisitions.

7. To certify and countersign bills of hospitals, apothecaries, and other purveyors, and those of private physicians, previous to forwarding the same to the physician-in-chief.

The duties of the physician-in-chief are:

1. To supervise the medical service of all the company's lines, and inspect the same as often as he deems proper.

2. To examine and countersign all bills for ordinary expenditures (those of hospitals, apothecaries, and other purveyors), and to advise superintendents of the operating and construction departments concerning extraordinary expenditures of the medical service (bills of private physicians, thermal-water establishments, indemnity for personal injuries, etc.), before transmitting them to the central bureau of accounts in the department of operation.

3. To consider all matters which are to be submitted to the superintendents of operation and construction, such as applications for extension of medical relief, for sending to mineral springs, and for indemnity on account of injuries; investigations and reports upon grave accidents; applications for positions in the medical corps.

4. He also receives the monthly reports of his subordinates, and consolidates their statements concerning the general health of the *personnel* and sanitary condition of the company's property into a general report, which he makes annually to the general manager, and in which he includes his own observations upon prevailing diseases and upon the medical service in general.

5. The physician-in-chief is, besides, charged with the general superintendence of the medical service; with receiving petitions or claims addressed to him by physicians, superintendents, or sick persons, in matters which concern the medical service; with the collection of documents which may contribute to improving the health of employés and the sanitary condition of the company's establishments; with assisting personally, in case of grave accidents, in the organization of relief, and with aiding by counsel and influence, in concert with the legal service, the adjustment of indemnities for personal injury; with making several times a year an inspection of the medical service and of the company's establishments; with suggesting any hygienic or medical measures which he may deem expedient to the company.

6. All petitions, documents, letters, etc., relative to the medical service, are sent to him through the administrative channel.

MEDICAL EXAMINATION.—No individual, except portresses, female gate-keepers, and sanitary employés, can enter the service of the company without previous examination by a company's physician, who gives him a certificate declaring the state of his general health and degree of his corporeal fitness for the particular position desired. The system of examination adopted by the Northern Railway Company of France is especially commendable. Any degree whatever of organic heart trouble, or any predisposition to tuberculosis, is cause for rejection. Particular attention is given to integrity of vision (with special reference to color-blindness), to freedom from varicose veins and hernia, among all men applying for train service—such as conductors, engineers, firemen, brakemen, and also switchmen, road-laborers, and shop-operatives. The ocular sense is examined by inspection of the eyelids, the lachrymal ducts, the conjunctiva, the cornea, and the pupil; by comparing the *visual field* of the candidate with that of the examiner; by determining *visual acuteness* by means of Snellen's test-types; by testing the *chromatic sense* with colored worsteds. (In the last case no one is condemned without re-examination by the physician-in-chief.) The sense of hearing is tested by the distance at which the ticking of a watch can be heard.

The list of ailments which are made absolute causes of rejection, or relative causes of disrating actual employés, comprises no less than sixty-eight affections. Six are cutaneous, including leprosy, lupus, and syphilitic ulcers. Four are maladies of the nervous system—convulsions, delirium tremens, paralysis, and insanity. Eye disorders number twelve, among which are myopia, color-blindness, and cataract. Well-marked deafness is the only ear-trouble specified. Affections of the neck comprise wry-neck, scrofulous and cancerous tumors, goitre, chronic laryngeal troubles, etc. Maladies of the thoracic walls (four in number) have reference to diseases of the bony structure; among those of the respiratory organs are included pulmonary consumption, chronic catarrh, and asthma; of the heart, we find organic affections of the walls, valves, and pericardium, and aneurism. There are six abdominal ailments, and eight of the genito-urinary organs, but not all of the last involve total disability. Constitutional infirmities include the scrofulous, scorbutic, tuberculous, and cancerous taints, and natural feebleness. From the above it appears that the examination partakes of the nature of that of recruits for the army and navy, and of that for life insurance, and on the whole is rather more searching than either. Its importance is apparent, when it is considered that the company assumes grave responsibility for the lives and health of its servants, while it thereby secures the permanent service of picked men, far above the average in efficiency and lasting qualities. The advantages to the men of the medical service, after admission to the company's employ, are so manifold (in relief, surgical and medical, in provision for the misfortunes of age and disability, and in permanence of engagement) that they are correspondingly attached to the company, and perform their duties with a fidelity not otherwise attainable, and a skill only acquired by long practice. At the same time risk of strikes, reprisals, and suits for personal damages is eliminated, as is also that of such accidents as are attributable to defects of the special senses and to sudden failure of vital organs on the part of those concerned in the movement of trains.

RELIEF.—Every employé, including females not examined, is entitled to relief (both attendance and medicines) in case of injury or sickness, except under circumstances hereafter to be mentioned. Whenever anyone declares himself ill, or is reported absent by reason of sickness, his foreman gives to him, or sends to the district physician, a ticket of attendance, detached from a record-stub, and joins to it a pass over the road, in case the patient is not near the physician's station. The physicians receive these patients at the station-house or at their own offices. They record upon a case-book the names, occupations, and residences of the out-patients, the nature and cause of their sickness, the remedies prescribed, the expected duration, and, after cure, the actual duration of disability for work; adding such observations as they deem useful to the patients and to the service. This record is examined by the physician-in-chief at every tour of inspection, and facilitates and governs future reference by the administration. When an employé, reported sick, is unable to leave the house, the ticket of attendance, inscribed "at domicile," with its precise location, is despatched to the physician, who then attends the patient at his own residence. In case hospital treatment is thought advisable, the patient has the option of home treatment at his own expense. On discharge from treatment the employé has his condition authenticated by the district physician to his foreman, without which the company is not responsible for the expense incurred. In a case of severe illness or injury, a company's physician may ask the counsel or aid of his colleagues in adjoining districts; or in emergency may call on a private medical man; but an account of the same must be rendered to the physician-in-chief.

An employé has the option of attendance by a private physician at his own expense. In an emergency certified by the man's foreman, when the company's physician cannot attend him, the private physician's bill is to be approved by the foreman and the district physician, and addressed to the physician-in-chief, who refers it to the administration. In any case, all such claim for fees ceases from the moment the company's physician is ready to attend the patient.

Medical and pecuniary relief for sickness or injury is limited to three months. After this the administration decides upon extending or discontinuing relief, or fixing

a time beyond which the employé goes out of the company's service. Every patient who exceeds his leave of absence without his physician's authority, or who unnecessarily requires the physician's attendance at his domicile, or is not at home when visited, is regarded as absent without leave and subject to penalty. The following are not entitled to medical relief: 1. Employés whose annual salary is more than twenty-five hundred francs. 2. Those who, though not required by the nature of their employment, dwell more than two kilometres from the establishments to which they are attached, in which case they can only require of the company's physician an authentication of their illness. 3. Those who, after discharge from attendance and before resuming work, again fall sick. 4. Those who were subjects of a chronic infirmity before entering the company's service. 5. Those whose illness results from their own misconduct (drunkenness, venereal infection, brawls, etc.). 6. Day-laborers and those working for contractors.

ACCIDENTS.—When an accident occurs upon the line, resulting in personal injuries, the physician of that district, and in his absence or in case of need those of the neighboring districts, and even private physicians, are summoned by telegraph to render aid, and, if necessary, organize an ambulance service. The company's physician will attend injured passengers until recovery, if they so desire. A circumstantial report of the accident is drawn up and transmitted to the physician-in-chief, and by him to the general manager. In an urgent case the foremen and employés are to follow the printed instructions concerning the first relief to be rendered while waiting for the doctor.

Whenever a district physician desires his place to be filled by one of his colleagues or by a private physician, he is to obtain permission of his chief. Each one is entitled to a free pass over his own and the two adjoining sections of the road, and the chief to a pass over the whole line.

MEDICAL STORES.—A relief-chest, with an amputation-case, a stretcher, and often a supply of medicines and surgical appliances, is deposited at the stations where workshops are located or locomotives are changed. Common relief-chests are deposited at other stations and establishments where they are liable to be needed. Purveyors of the company, such as apothecaries, druggists, surgical-instrument-makers, etc., agree to a written tariff of prices, and sell to employés of the company by the same tariff whatever articles they need for their personal use. All bills are presented quarterly to the district physicians, and after approval are transmitted to the physician-in-chief.

PRINTED INSTRUCTIONS TO EMPLOYÉS.—These relate: 1. To the principal hygienic precautions which should be observed by individuals to avert preventable diseases and accidents. 2. To the chief measures which are to be used on the spot while waiting for the doctor, in case of the most common accidents and maladies. 3. To the mode of employing the contents of the relief-chests and of the medicine-chests at the station-houses, especially those which are in daily use or can be obtained without a physician's prescription.

The Eastern Railway of France has some additional provisions, which are worthy of consideration, if not of commendation. All trains are provided with relief-chests, containing medicines and surgical appliances for use in case of accidental injuries to any persons travelling thereon. Sick employés continue to receive full pay during illness not exceeding eight days; from this time up to two months of disability for work they are allowed half-pay. Beyond two months the allowance is at the discretion of the administration. In case of death the company grants to the widow or orphans a sum equal to two months' pay, and assumes the expense of burial. In special cases further pecuniary relief to the family may be granted. But these allowances are made only to permanent employés. Day-laborers receive medical attendance and medicines, together with half-pay, during two weeks of disability, which may be extended if the disability arose strictly in line of duty.

A Provident Fund has been established among the people of this company for the purpose of supplementing the relief granted through the regular medical service, in case of sickness or injury, to employés or to their families in case of death. Its benefits accrue only to the contributors, and they receive half-pay for two months after the company's allowance has expired. In addition the family receive from the fund a sum equal to that allowed by the company. In case of permanent disability, besides allowances already mentioned, the invalid will recover all sums previously contributed by him to this relief fund; otherwise the relief is limited to one year's contributions. Relief can be refused when the disability has arisen from the person's own misconduct; and when he leaves the company's service no claim for reimbursement is entertained. Whenever the Provident Fund fails to meet all demands, the company advances the needed sum, and provides for repayment by increased assessment upon contributing members. Any surplus goes to the Pension Fund.

In France, the Netherlands, and Italy, the families of railway employés are not provided with medical relief by the railway medical service, but this is generally the case in Austro-Hungary, the German Empire, Sweden, and Spain. The regulations usually require employés to be contributing members to some association, and deductions are made from their monthly wages of one to two per cent. to the credit of the medical fund. This is supplemented by a contribution of a similar amount by the company—sometimes equal, and sometimes one-half. In the Austro-Hungarian Empire district-physicians instruct the men in the use of instruments, dressings, and certain medicines, so that they may know how to act in an emergency in the absence of a medical man, and how to assist him in case of need. In the German Empire station-agents and train-conductors are provided with printed instructions, and are required to familiarize themselves with bandages and simple dressings. In this country provision is made by the different companies for the care of those permanently disabled by sickness or injury while in the discharge of duty. In case of death their families are provided for. Certain classes of employés are also entitled to retire upon a pension, after service for a period of not less than ten years. Their widows are also entitled to a pension, and their young children to an allowance for their rearing. There are also regulations for the cleansing and disinfection of cars used for the transportation of live animals, as soon as emptied. All these regulations in the German Empire were drawn up by a government official, and have the force of law.

In the principal railway company of Northern Italy there are two associations of the employés which all are required to join, except those whose annual pay amounts to more than two hundred and forty dollars. One of these is for mutual assistance in case of injury or sickness, to which each member contributes one and a half per cent. of his monthly wages; the other provides retiring pensions after a fixed term of service, or in case of permanent invalidism, and calls for three per cent. of the wages. Want of space does not admit going into details in these pages. From the former, members receive during illness and convalescence, after one month's contribution, one-third of their wages; after two months' contribution, one-half; after three months' contribution, two-thirds of their wages. This relief terminates in three months, but may be renewed by decision of the committee, provided the state of the funds admits. In Sweden similar allowances of pay to sick and injured employés is made by the government railways; and some provision is made for their families in case of sickness, injury, and death, both by the companies and by their own associations.

In the United States a railway medical service first became systematized in 1869, on the Central Pacific Railway, and its plan has been imitated by other roads running through sparsely inhabited and extensive districts. A hospital was erected by the company at Sacramento, to the benefits of which all employés are entitled, and for

the support of which all have to contribute fifty cents a month. The Baltimore & Ohio Railroad has an Employés' Relief Association, to which all must contribute according to the amount of their pay. For this purpose they are divided into five classes; the lowest, receiving $35 and under per month, contribute one dollar per month, and are entitled to 50 cents a day during disablement not exceeding six months; while the highest, receiving $100 or more, pay five dollars a month, and receive $2.50 a day in relief. These figures apply to those employed in train service; in other branches the contributions and benefits are one-fourth less. After six months of disablement the allowance for relief is reduced to one-half. In case of death from accident, the legal representative is entitled to an allowance of from $500 to $2,500, according to the monthly contributions; in case of death from ordinary sickness, the allowance is one-fifth of the above. The company has no hospitals of its own, but has contracts with hospitals at the principal cities, to which its people may be admitted on favorable terms. The association pays for surgical attendance at the hospital, and the member for his board, which is more than met by his relief allowance. The company, at the beginning, appropriated $100,000 as a foundation to the relief organization, the interest of which is annually available. The salaried officers consist of the secretary of the association, who is the medical superintendent, and seven inspectors, who are assigned to specified districts, which they are constantly traversing to investigate cases of disability, the sanitary condition of the company's establishments, etc. They also attend persons injured by the casualties of traffic, both employés and passengers, make physical examination of applicants for employment, vaccinate those requiring it, and provide appropriate remedies for the relief of such disorders as malarial fevers and intestinal irregularities, wherever they may be found prevalent. There are also pension and building funds, to which employés may contribute at option and enjoy corresponding privileges.

Another system in use upon several American railroads has reference solely to relief, at the expense of the company, to sufferers from accidents, without provision for ordinary sickness. The only salaried officer is a chief surgeon. Contracts are made with local practitioners, at convenient intervals, to attend at fixed rates those accidentally injured. The district surgeons have free passes over their own territory, which is the most valuable consideration for the appointment. The Denver & Rio Grande Railroad, alone of American companies, provides relief-boxes for all trains, containing such medical and surgical supplies as are liable to be needed on the route. This company has its own hospitals, and requires a physical examination of all employed in the movement of trains.

It is evident that railway medical service in this country has nowhere attained the degree of efficiency and utility found on the continent of Europe. Probably the minuteness of details there exercised would be here found incompatible with American notions of personal liberty. There can be no dispute that an organized system of relief to sufferers from the casualties of traffic is demanded of all companies of respectable magnitude, as a measure of both humanity and economy. It is the cheapest mode of exoneration from legal responsibility to give all possible relief before it is demanded. When once this necessary provision is made, other desirable features can be added without great expense, making use of the same medical officers. There can be no doubt that sure relief to employés in ordinary sickness is a great advantage to them, and its appreciation conduces to such increase of content and fidelity on their part as to warrant a large outlay by a company to furnish a foundation for an organized system. The advantage is increased when the same privilege is extended to the man's family. It tends to permanence of engagements, and forestalls strikes and reprisals. The expense of this feature is met by deductions from monthly wages, which are cheerfully submitted to when the men find their advantage in the system. Physical examination of trainmen is required for the security of travellers from such accidents as are liable to result from defects of sight and hearing, and from sudden failure of vital organs; and, as a measure of protection to the relief-funds, it must be required of all who participate in its benefits. Relief-chests will not often be needed; neither are pocket-pistols; but, when occasion requires, both are urgently wanted. It is indisputable that certain intelligent employés ought to know how to use the contents of a relief-chest, and that they ought to be instructed by a medical man. Attention to the personal hygiene of employés, and to the sanitary condition of buildings, grounds, railway carriages, etc., is also a proper duty of the medical staff, and involves no expense comparable to its benefits.

It is evident that railways are liable, unwittingly, to become carriers of contagion, both of human beings and of animals transported in their cars, and that all reasonable means should be used to prevent so undesirable an event. Small-pox, cholera, and glanders may be mentioned as examples of such transportable diseases. Vigilant medical men in the service of a company would generally be able to give timely warning, so that the necessary precautions might be taken to keep infection at a distance; or, in case of actual admission of choleraic, variolous, or glandered subjects, that proper measures of disinfection might be employed. The prevention of such diseases is vastly more important than their cure, and in general the preventive functions of a railway medical service should be regarded as the most useful part of its duties. It is time now, near the dawn of the twentieth century, to recognize in medicine, as in an army and navy establishment, that its greatest achievements are in forestalling the ills which it was formerly expected only to redress. *S. S. Herrick.*

RAILWAY SPINE. This ambiguous and misleading term has been for many years applied to the large class of cases in which pain and stiffness in the back, and various symptoms referable to the nervous system, follow trauma in the form of blows, falls, and collisions. The name was given, and has come into general use, because railway accidents are among the most common causes, especially in those cases which come into prominence on account of litigation. The expression is ambiguous in that it gives no clew to the seat of the morbid process, as to whether the spinal cord, its membranes, its bony and ligamentous coverings, or the overlying parts, are affected; misleading in that it directs attention to the spinal cord, an organ which has probably far less to do with the trouble than has been generally supposed in the past. It should be premised that there is still considerable variance among those who have written on this subject, as well as in the prominent text-books. The views expressed in this article far from represent the unanimous opinion of authorities. They are, however, practically in conformity with the principles first enunciated by Page, to whom, more than to any other, is due the credit of rescuing the subject from utter confusion.

The symptoms under consideration follow accidents which cause a jar to the body, whether received from a blow on the trunk, head, or elsewhere, or from a fall upon the head, back, buttocks, or other part of the body. They generally vary in intensity with the violence of the jar, but in persons of neuropathic tendency the slightest possible shock may be the exciting cause for the most marked symptoms—a fact which lets much light on the pathology of the affection, in that it points, at least in these cases, to traumatic hysteria or neurasthenia, rather than injury to the spinal cord. The prevailing theory in the past, and perhaps even up to the present, has been that concussion of the spinal cord lies at the bottom of the trouble—a theory which has done much to perpetuate the name. This diagnosis, however, if ever allowable, is certainly, in the vast majority of these cases, not tenable.

Leaving out of consideration the symptoms arising from structural injury (hæmorrhage, myelitis, meningitis), which have been falsely attributed to concussion of the spine, but which should be sought under their appropriate titles, we find that the patients suffer, as a rule, first,

from more or less marked symptoms (which need not be here enumerated) of shock, and afterward, for a longer or shorter period, complain of soreness, pain, and stiffness in the back, and of the almost endless variety of nervous symptoms, which have been commonly accredited to spinal concussion. Included under this title have appeared not only such symptoms as pains in the back and elsewhere, loss of sexual power, general malaise, and weakness of the extremities, but also headache, sleeplessness, loss of memory, vertigo, inability to confine the attention, and similar symptoms, which would point rather to the brain than to the spinal cord, if any one part of the central nervous system were to be credited with the entire pathology of the disturbance. Recent writers (notably Page) have expressed great doubt as to the liability of the spinal cord to injury, as long as its bony case remains intact, although not denying that it may occur exceptionally. This view seems far more satisfactory than that of the writers who favor spinal concussion, when we consider the fact that the spinal cord, an organ of extremely light weight, hangs suspended in a cavity much larger than itself, the intervening space being filled out by areolar tissue, membranes, cerebro-spinal fluid, and a plexus of veins, all of which protect it in such a way that no ordinary blow is liable to affect it as long as the vertebræ are uninjured; furthermore, the automatic centres situated in the spinal cord represent a less delicate set of functions than those of the brain, and are, therefore, probably less liable to be thrown out of balance by a moderate jar. The brain itself, moreover, is mechanically so placed as to be much more susceptible to damage from violence than the spinal cord, being heavier and less thoroughly protected by its bony covering. On *à priori* grounds, therefore, we should expect the brain, rather than the spinal cord, to be the principal sufferer from a jar to the whole body, and the analysis of the symptoms, with this fact in mind, shows that the spinal cord is not even an essential factor.

Leaving for a moment the question of strain of muscles of the back, and of the ligaments of the vertebræ, which are frequently present in these cases, and which have perhaps been the principal factor in drawing attention to the spine, we find that most of the symptoms of so-called railway spine admit of satisfactory explanation by disordered function of the cerebral centres, and that they are closely allied to, if not identical with, the recognized symptoms of the functional nervous disturbances included under the names hysteria, neurasthenia, and hypochondria. Such symptoms as hopelessness, morbid fears, sleeplessness, mental irritability, and inability to confine the attention, certainly come under this category, as well as asthenopia, amblyopia, nervous deafness, and other disturbances of special sense. Among the other innumerable symptoms we find pains in the back, sensitiveness of the spine to pressure, weakness in the back, tenderness of the scalp, heaviness of the loins and limbs, flushes and chills, mental and physical hyper-sensitiveness, anæsthesia, and impotence. These are all recognized symptoms of functional nervous disease, and point to weakness and irritability of the entire nervous system, more especially the brain and the sympathetic, and the term spinal concussion, like that of spinal irritation, intended, as it undoubtedly often is, to convey the idea that disorder of the spinal nerve-cells, or of the meninges, furnishes the basis for the trouble, is certainly misleading. Sensitiveness of the spine to pressure has probably nothing to do with the cord in the large majority of these cases. The tender spots over the spine represent simply the ramifications of the sensory nerves of the region implicated, and it is a significant fact, in this connection, that these sensitive spots are common in the lower lumbar, sacral, and coccygeal regions, far below the termination of the cord. Apart from the sensitiveness of the tissues from sprain, these regions of hyperæsthesia fall into the same category as the tender spots on the scalp, pointing to cerebral irritability. The feeling of weakness in the back means, probably, that the muscles of the back are wearied in holding up the vertebral column, just as any other muscles may tire of performing their function, and we have no reason for connecting these sensations with the spinal centres. The same is true of the sense of heaviness in the loins and limbs, of which these patients often complain. Morbid fears, vaso-motor irregularities, and extreme sensitiveness to cold, heat, medicines, or other influences, may all be classed together as common to hysterical, hypochondriacal, and so-called neurasthenical patients. Such patients report the most severe symptoms following directly upon the application of cold water or electricity, or upon the exhibition of drugs in absurdly minimal doses. While these symptoms are by no means to be classed as simply imaginary, they are obviously to be explained by perversion of cerebral function. One of the most common symptoms complained of is loss of sexual power and desire, but this is not necessarily connected with the spinal cord, for the lower centres for erection and ejaculation are under the influence of the brain, so that this reflex may be started even by a thought or inhibited by a fear. Irregularities in micturition are frequently noticed, as well as palpitation, præcordial distress, and disorders of digestion differing in no respect from symptoms of functional vesical, cardiac, and digestive derangement met with in neurasthenia and hysteria. In some cases appear paralyses and contractures, anæsthesia, hyperæsthesia, and convulsions; the motor disorders not being limited, as a rule, to any muscle or group of muscles, but affecting a whole limb or more; the sensory disturbances being generally bounded by a line not representing the distribution of any particular nerve, and often affecting an entire half of the body (traumatic hemianæsthesia, first observed by Putnam). These conditions correspond with the typical motor and sensory symptoms of hysteria, the special senses being also generally affected in the manner characteristic of that disease (see Hysteria). Any or all of the symptoms enumerated under hysteria may be present, and need not be here recapitulated. It is true that these symptoms sometimes persist for a long time; this does not, however, militate against the diagnosis of hysteria, nor does their occurrence in men as well as women, to both of which facts Charcot has drawn special attention.

Apart from the neuralgic pains and hyperæsthetic spots on the back, the majority of the patients complain of constant pain and soreness in the back and sensitiveness to deep pressure over both the vertebral column and the muscles of both sides, most frequently over the lumbar regions. The pain is increased on movement, especially by bending and twisting the trunk. This symptom, whether accompanied or not by hypersensitiveness of the back to the light touch, points to strain of the muscles of the back, and sometimes of the ligaments of the vertebral column. It should not, therefore, though among the most persistent and troublesome of the symptoms, be attributed in any degree to disorder of the spinal cord or its membranes. A similar condition may obtain in the muscles of the neck and the ligaments of the cervical vertebræ, as well as in any part of the body which is liable to strain from either direct violence or muscular effort.

PATHOLOGY.—As to the exact pathology of those symptoms which are referable to the nervous system, we are still in the dark, as we are regarding the pathology of hysteria, neurasthenia, and hypochondria. Post-mortem examination reveals nothing, and we are forced to adopt the term functional disturbance of the central nervous system, regarding the brain as the organ most seriously implicated, without venturing to theorize as to whether the disorder is due to malnutrition, vaso-motor irregularities, molecular disturbances, or perhaps to reflex irritation from injury of abdominal or other organs. Certain writers (Westphal, Oppenheim) believe that chronic structural changes (widely diffused sclerosis) may supervene, and cause the persistence of symptoms sometimes seen. This matter must be considered as still under discussion. There can be no doubt, however, that atrophy of the optic nerve can follow simple concussion.

DIAGNOSIS.—The utmost care is necessary to exclude organic lesion of the central nervous system, as, for ex-

ample, hæmorrhage into the brain or cord, myelitis, and meningitis, as well as injury or disease of the vertebræ, especially fracture, dislocation, and caries. Before eliminating organic disease we should look carefully for such symptoms as local atrophy and coldness, rigidity, alteration of electrical reactions, ankle clonus, and irregularity of the pupils. Bed-sores and cystitis point to organic disease, and are practically never present in the class of cases here considered. When organic disease is demonstrated, the case should be classed and treated accordingly. Great care must be taken to exclude, as far as possible, simulation and exaggeration. The difficulty in detecting deceit is especially great on account of the ease with which the subjective complaints may be assumed and kept up. It must also be remembered that these patients may fall into a state of prolonged invalidism from simple lack of will-power, and even where no deceit is definitely planned the prospect of large damages naturally places a premium on inertia. We should always seek to discover, then, first—are the symptoms real, feigned, imagined, or exaggerated? secondly, if real, are they functional or organic? The variety of symptoms which may be feigned is so great that the study of their detection can hardly be entered upon in this article. Cases should be regarded with suspicion in which the symptoms have not appeared until the lapse of considerable time after the accident, allowing, however, a certain time for the patient to recover from the benumbing effects of the shock. Cases which appear to grow worse and worse up to the time of settlement of claims for damages should be examined with special care, and will often be found to improve rapidly after the claim is adjusted.

Treatment.—The treatment differs at the outset in no respect from that of shock, and later from that of strain, whether of muscles, ligaments, or both, and from that of hysteria, neurasthenia, or hypochondria, according as the symptoms of each disorder predominate. The treatment of these diseases is considered elsewhere.

Prognosis.—The prognosis of these traumatic functional disorders is better than that of similar disorders resulting from natural causes, and the tendency of the nervous symptoms, as well as that of the strain, is in general toward improvement, rapid or gradual, continuous or intermittent, according to the severity of the shock, the surroundings of the patient, and the various influences which govern the course of all functional nervous derangements. The previous condition of the patient should always be considered in making the prognosis, inasmuch as rapid and steady improvement is more to be expected in the case of a person previously robust, than in that of one already of a neurotic temperament or broken down by overwork, anxiety, or pre-existing disease. The exact period required for recovery can never be prognosticated; while the milder cases may run their course in days or weeks, others may last months, or even years, and in exceptional instances the symptoms, especially those referable to the back, seem to cause annoyance for an almost indefinite period of time, even when no question of damages or other inducement to invalidism is present. Permanency of the nervous symptoms is, however, of great rarity, excepting in persons already suffering from, or on the verge of, hysteria, neurasthenia, or hypochondria, where the trauma acts merely as an exciting or aggravating cause. It would seem that the prognosis which has found its way into the text-books, that these cases may grow worse and terminate fatally, has arisen from the old confusion between organic and functional cases. A prognosis which belongs, except in the rarest instances, only to the cases of organic lesion of the nervous system, should hardly be made to cover all indiscriminately. This prognosis accords an undue importance to nervous injuries resulting from railway and other accidents, inasmuch as in the vast majority of cases we have to do with such functional disorders as above described, either existing alone or in combination with strain of the muscles of the back and of the ligaments of the vertebræ.

G. L. Walton.

RÂLES. This term is applied to certain abnormal sounds heard in the chest. It is customary with many authors to speak of *dry* and *moist* râles. Sibilant and sonorous breath-sounds are called dry râles, although there is no more reason for calling these sounds râles than there is for applying the same term to cavernous breathing. Certain authors also call these forms of breathing rhonchi, and use the word râle to designate only the moist sounds. Rhonchus, again, by others, is used as exactly synonymous with râle.

The causes of these abnormal sounds vary considerably. We may have a considerable accumulation of exudation in the trachea and larger bronchi, producing large bubbles, or the smaller bronchi may be more or less filled, giving rise to small bubbles, or perhaps the sounds may be produced in the alveoli themselves. Râles may also be produced by the rubbing of roughened pleural surfaces, by the presence of fibrinous exudate on the pleura, and by the stretching of pleuritic adhesions.

Coarse Mucous Râles are coarse bubbling sounds produced in the trachea and larger bronchi. They are heard with both inspiration and expiration. They may sometimes be made to disappear for a time by causing the patient to cough. Sometimes, especially in children, they may produce a fremitus easily felt through the chest-wall. They are heard most commonly with acute bronchitis in its exudative stage, and with broncho-pneumonia, also with chronic bronchitis and phthisis, some cases of œdema of the lungs, lobar pneumonia, compression of bronchi or trachea due to neoplasm or aneurism, some cases of pleurisy with effusion, and empyema, especially with perforation of the lung.

Fine Mucous Râles are sounds of the same quality as the former, but finer. They are heard under the same conditions.

Subcrepitant Râles.—These are fine, high-pitched, bubbling sounds, heard during both inspiration and expiration. They may be produced by the bursting of small bubbles in the finest bronchioles or air-passages, or they may be caused by fibrin on the pleura, and by pleuritic adhesions. The cause of this râle has been a matter of considerable dispute. On the one hand, it is held that the sound is invariably produced in the finer air-passages; on the other, that pleural changes alone can give rise to it. The advocates of the former view hold that sounds resembling the subcrepitant râle may be produced in the pleura, but that a good ear can distinguish these from the true subcrepitant, by a slight difference in quality. Believers in the second dictum say that there is not enough motion of the air in the finer air-passages to give rise to the râle. Both of these views are extreme. There are cases in which the subcrepitant râle is heard which show, *post mortem*, nothing but pleurisy as a possible cause, and there are cases of œdema of the lungs, with no pleuritic changes, in which this râle has been clearly heard, and in which the serum in the lungs is the only demonstrable factor in its production. It cannot be denied that the sound may be due to either of these causes. This râle may be heard in pleurisy; bronchitis of the smaller tubes; broncho-pneumonia; lobar pneumonia during the stage of resolution, and occasionally during other stages; phthisis; and œdema of the lungs.

Crepitant Râles.—These are very fine sounds heard only at the end of inspiration, and sounding very near the ear. They occur in abrupt explosions. They are much finer than the subcrepitant râles, and are usually compared to the sound produced by rubbing a lock of hair between the fingers. The causes of this râle are the rubbing together of inflamed pleural surfaces, the entrance of air into ultimate bronchioles or alveoli, the walls of which are partly stuck together by exudate, or perhaps the breaking of very fine bubbles. Of these three possible causes the first seems most common, and it is not unlikely that this is really the only cause. It is conceivable that if the pleura be coated with a thin layer of sticky exudation, its surfaces will tend to stick together until the end of inspiration, and then, in slipping over one another, give rise to the sound. This râle is often said to be pathognomonic of acute lobar pneumo-

nia. This is not so. The râle is frequently heard in the first stage of this disease, but it is also heard in pleurisy, broncho-pneumonia, and phthisis. Taken in connection with a rational history of acute lobar pneumonia, the râle is of great value as a sign, especially if with it other signs be found, but it is not to be called pathognomonic.

PLEURITIC FRICTION SOUNDS are râles produced in the pleura when it is diseased. They may be of a rather moist, grazing character, or may be creaking and dry. They may be heard in all diseases in which the pleura is involved. As has been mentioned, the pleural surfaces, when diseased, may give rise to crepitant and subcrepitant râles.

PLEURITIC ADHESION SOUNDS.—In some cases of old pleurisy, with adhesions, peculiar sounds are heard, which may be accurately imitated by applying one end of a rubber band to the ear and stretching it. The adhesion sounds are probably produced by stretching of old adhesions.

THE METALLIC TINKLE is a sound resembling that produced by pouring water in drops into a bottle. It is produced either by drops of fluid falling from the roof of large cavities in the lung, or the cavity of hydropneumothorax, or by bubbles breaking in fluid under similar circumstances. In different cases one or the other of these causes may produce the sound. It is heard over some large cavities, and, in some cases of pneumo-thorax, may occur either when the patient speaks or with the breathing.

GURGLES are coarse râles which are more liquid than mucous râles. They are sometimes heard in bronchitis, in some cases of solidified or compressed lung, and in some cavities.

THE MUCOUS CLICK is a peculiar dry sound, occasionally heard at the end of inspiration. Its cause and significance are not clear.

DRY AND MOIST CRACKLES are sometimes mentioned. They are difficult to distinguish from subcrepitant râles.

SIBILANT BREATHING, sometimes called sibilant *rhonchus* or râle, is a whistling or hissing sound heard in cases where a bronchus is narrowed by inflammatory thickening of its mucous membrane or by other causes.

SONOROUS BREATHING is produced in the same manner as the former. It is of lower pitch and softer quality.

J. West Roosevelt.

RANULA, a cystic tumor in the floor of the mouth, formed by the dilatation of one or more of the acini of the anterior lingual glands (Ward[1]), known also as the "Blandin-Nuhn" glands (v. Recklinghausen[2]), situated at the under side of the tongue on either side of the frænum linguæ, near the apex.

This definition is founded on the result of a characteristically thorough investigation, by the accomplished Strassburg pathologist, of a typical ranula accidentally found at a necropsy made in his pathological institute. The cyst, about the size of a pigeon's egg, was found on the under side of the left half of the tongue, extending to a little beyond the median line upon the right side, and penetrating into the intermuscular spaces in different directions. The wall of the cyst was of a nearly uniform thickness of from one to three millimetres; the internal surface was nearly smooth, except in the upper part, where, anteriorly, toward the apex, there was a prominence of some five millimetres in height, upon which were two furrows; one of these, situated near the top of the prominence, allowed the passage of a bristle to the depth of two and a half millimetres, while the other, situated near the base and away from the apex, was impervious. The cyst was everywhere colorless and translucent, except at the inferior part, where there was an opaque spot of about twenty millimetres in diameter, of a brownish color, having at its edges two more cysts, each about the size of a pin's head. The ducts of the various salivary glands, Wharton's and Rivinus', as well as Bartolini's, were all to be traced outside of the cyst, having no other relation with it than proximity. The microscopic examination showed that the epithelial lining of the cyst-wall was in two layers, the inner one of ciliated cylindrical epithelium, and beneath this a layer of small polygonal cells with large nuclei. The cyst contained a clear, somewhat thick, glairy, and viscid mucus, faintly yellow in color. The morphological elements were cells of an epithelial character in various stages of "colloid" degeneration, large brownish granular bodies, and numerous hyaline corpuscles, among which were some quite large, of a diffused, faint greenish-yellow shade, permeated with countless "vacuoles." The chemical examination showed a considerable amount of mucus, but no evidence either of sulpho-cyanide of potassium or of any fermentative material for the saccharine conversion of starch; therefore the fluid was not saliva. This confirmed the investigation of Besanez,[3] made in 1845.

Ranulæ, in general, present themselves as translucent pink or bluish tumors, generally globular in shape and fluctuating, lying either wholly in the mouth or between the mouth and chin, according to their size. They project into the floor of the mouth from beneath the tongue, at first quite to one side of the frænum linguæ; but as they grow to fill the mouth they elevate the tongue, push it over to the opposite side, and in time present themselves against the teeth in front, and may even prevent their closure. They push the frænum toward the opposite side, but may project beyond it, giving the appearance of two tumors, or of one tumor divided into a larger and a smaller portion. With this filling up of the mouth the interference with speech and deglutition is very great. The elder Cline[4] relates the case of a person who was in great danger of immediate suffocation by a large ranula which thrust the tongue back into the fauces. When not interfered with the tumor will project in the neck below the angle of the chin, and fluctuation may be felt in this situation. When the tumor is large the deformity of expression is great, and presents a certain resemblance to the mouth of a frog, the pale bluish, translucent hue adding thereto; hence the name, from *rana*, frog (*Froschgeschwulste*, Germ.; *grenouillette*, Fr.).

Cysts of other organs than the Blandin-Nuhn glands are also found in this situation. Wharton's duct may be dilated by the damming back of the secretion of the submaxillary gland from the formation of a salivary concretion in the duct, either at its orifice or in its course, and dermoid cysts, often of considerable size, are also found. The latter are especially interesting pathologically, as they undoubtedly represent here the remains of a fœtal organ which normally entirely disappears. The branchial fissures of the fœtus are normally obliterated early in fœtal life, but occasionally a fold of the tegumentary or epiblastic layer becomes included in the deeper tissues in the process of closing in from the sides to form the face, and finally becomes entirely separated from its attachment to the external skin. It may remain quiescent, giving no evidence of its presence, or the cells of the epithelial lining may be excited to growth and the interior become filled with the products, consisting of broken-down epithelium, fat, cholesterin crystals, and débris, *i.e.*, the usual contents of cysts developed from the dermoid layer. Indeed, hairs, bone, and teeth have been found in them.[5] These dermoid cysts, however, do not spring from the same point as do true ranulæ. They are situated either in the median line, between the two genio-hyo-glossi muscles, or between one of these and the mylo-hyoid; but as they grow they extend upward into the floor of the mouth, or downward in the neck, as far, perhaps, as the larynx.[6]

DIAGNOSIS.—These various tumors present points of differentiation sufficiently marked, usually, to allow them to be recognized, and as the treatment of each is different, it is important to have them well in mind. The positions of true ranula and the dilated Whartonian duct are, by the time they have aroused sufficient attention to be brought to the notice of the surgeon, very nearly the same; they both lie just under the tongue, to one side of the frænum, and filling up the floor of the mouth, elevating the tongue above it, and appearing as a thin-walled, fluctuating, and translucent tumor. In the case of the ranula, this tumor has upon its surface

Wharton's duct, the orifice of which can usually be detected near the median line, and into which a fine probe or bristle may be passed, and seen to glide along the surface to the submaxillary gland, external to and beyond the cyst. Careful search will often, also, reveal the orifices of the sublingual gland, the ducts of Rivinus. Blood-vessels are frequently seen coursing in waving lines over the cyst. When Wharton's duct is the seat of the tumor, the entrance of the probe into it will be prevented by the obstacle blocking it up, be it salivary concretion or inflammatory product, and removal of the obstacle will usually allow the escape of the fluid. In these cases there are usually considerable pain and circumjacent swelling, with other evidences of inflammatory action in all the parts implicated; the floor of the mouth is hot and tender, the tongue is painful on motion, and under the jaw the submaxillary gland is swollen and tender.

The clinical features of the dermoid cyst are different; indeed, there should be no confusion between them, but inasmuch as, from their situation and gross appearances, they are sometimes described as ranula, it is well to point out their differences. The wall is usually thick and firm, the contents may be quite thick, even mortar-like, sometimes purulent, or the contained fluid may be thin or viscid. There may be fluctuation, but it is less distinct than in ranula, and the surface often pits on pressure. The tumor is situated more deeply under the muscles of the mouth, and, when presenting under the jaw, is imbedded among those of the neck, and may penetrate even as far down as the larynx. In the mouth it arises nearer the median line, although as it grows its origin becomes obscured, and may not be readily determined at the time that the case comes under the observation of the surgeon.

Treatment.—No other than operative interference is of any avail in the treatment of these cysts, and it is usually necessary to do more than simply to evacuate their contents. If it be a dilated *Whartonian duct*, the removal of the concretion blocking up the orifice is usually sufficient; but this requires some care, as it is often very brittle, and if any fragments remain they set up a good deal of irritation in the duct itself, and serve as nuclei for further collections. Therefore, an opening should be made in the duct sufficiently large to "shell out" the stone entire. As these are occasionally quite long, it may require a considerable incision in the length of the duct, but this is preferable to making a small opening and endeavoring to drag the stone out; for if this is attempted it is liable to break, to the subsequent annoyance of both patient and surgeon. It is better, when practicable, to remove the *dermoid cyst* entirely, though, when it extends deeply and has very firm attachments, this will be difficult, and may be impossible with safety to the patient.

When not large it is usually easiest to make a free incision through the cyst-wall—whether in the mouth or under the chin depends upon its accessibility—and evacuate the contents. When these are thick and tenacious this may be a matter of some difficulty. After this, the cyst-wall being tolerably firm, it will bear considerable dragging upon, and may be enucleated with the handle of the scalpel, aided by occasional snips with the blade or with scissors. Cases are occasionally met, however, in which the operation of entire removal is both difficult and dangerous. In Mr. Mayo's[6] case the tumor extended down nearly to the clavicle, passing between the sterno-mastoid muscle and the trachea. After scooping out the contents and removing a part of the wall, he left the rest to suppurate, first filling the cavity with lint soaked in turpentine, in order both to arrest the hæmorrhage and to hasten the suppuration. The patient recovered after a considerable time.

Sir William Fergusson's[7] case filled the mouth so as to threaten suffocation, keeping the teeth forcibly apart and projecting prominently under the chin. He feared to leave "a sac so large and thick to the certainty of a violent inflammation," . . . and "resolved instead to attempt the extraction of the whole cyst." Incisions were made both in the mouth and in the neck, but "the sac was so amalgamated with the surrounding tissues that a free use of the knife was required." No large vessel was cut, but there was much loss of blood both at the operation and subsequently; the ultimate result, however, was entirely satisfactory.

The true thin-walled ranula requires a different treatment. Simple incision is not sufficient, for the edges of the wound usually reunite and the cyst forms again. The wall is also too thin to allow its enucleation *in toto*. A seton introduced through its walls, and allowed to remain a couple of weeks, more or less, will sometimes, but not always, cure it, and is to be tried first. This failing, some surgeons recommend the removal of a large part of the thin wall, in the expectation that the remainder of the cyst will collapse and the walls unite, to the obliteration of its cavity; but, like the seton, this often fails. A sort of plastic operation has, therefore, been tried, and is usually successful. This consists in forming a triangular flap by a couple of converging incisions in the anterior wall, and fastening the apex by two or three sutures to the opposite wall; adhesions are thus formed, and the cyst is kept open until the wall shrivels up. Sonnenberg recommends that the remainder of the gland be dissected out of its bed in the apex of the tongue, thus preventing the development of any other cysts afterward. This is occasionally done, with very satisfactory results, when milder measures have failed.

RAPE-SEED, OIL OF. (*Oleum Rapæ*, Ph. G.) This is a nearly non-drying oil, obtained from several cultivated varieties of *Brassica* (order, *Cruciferæ*), related to turnips and cabbages, and extensively raised in Europe for their seeds, from which it is extracted by pressure.

Rape-seed, or colza, oil, is a thick, yellowish liquid of no very characteristic odor or taste. It is extensively employed as a lubricant, as a salad oil, and as a cheaper substitute for olive-oil generally. In this country its place is taken by cotton-seed oil. Purified, it is put to cheap uses in German pharmacy, such as in making liniments, plasters, etc.

Allied Plants.—Turnips of various sorts—summer, winter, rutabaga, etc.; cabbages, cauliflower, Brussels sprouts, and kohl-rabi; also mustard and radishes. For the order see Mustard.

Allied Drugs.—All the fixed oils; see Olive-Oil.

W. P. Bolles.

RASPBERRY. (*Rubus Idæus*, U. S. Ph.; *Framboise*, Codex Med.) The fruit of the garden raspberry. *Rubus Idæus* Linn., order, *Rosaceæ*, is a well-known European straggling shrub, cultivated both there and here for its delicious fruit. It has not the slightest medicinal value, and is only used in syrup, etc. (*Syrupus Rubi Idæi*, U. S. Ph.), as a pleasant vehicle, or a flavor for aërated waters, etc. The leaves of raspberry are a household astringent, like blackberry root, etc.

Allied Plants.—The leaves of *R. fruticosus* Linn. are in the Codex (*Ronce Sauvage*). They are astringent. See Roses, Blackberry, etc.

Allied Drugs.—Fruits and fruit-syrups in general.

W. P. Bolles.

RAVENDEN SPRINGS. *Location*, Ravenden Springs, Randolph County, Ark.

Access.—By the St. Louis, Iron Mountain & Southern

Railway (Missouri Pacific System) to O'Kean, then by stage.

ANALYSIS.—One pint contains:

	Grains.
Carbonate of magnesia	0.560
Carbonate of lime	0.576
Carbonate of lithia	0.157
Chloride of sodium	0.273
Chloride of magnesium	0.373
Chloride of lime	0.155
Sulphate of lime	trace
Sulphate of alumina	0.295
Silica	0.103
Iodine and iron	trace
Organic matter	0.232
Total	2.724
	Cub. in.
Carbonic acid gas	2.68
Atmospheric air	1.66

THERAPEUTIC PROPERTIES.—These are mild alkaline waters, sufficiently charged with natural carbonic gas to render them very agreeable.

The springs are situated in the northeastern part of Arkansas, in a picturesque country abounding in game and fish. *G. B. F.*

RAWLEY SPRINGS. *Location and Post-office,* Rawley Springs, Rockingham County, Va.

ACCESS.—By the Baltimore & Ohio (Harper's Ferry & Valley Branch) Railroad to Harrisonburg; thence by stage to the springs, ten miles.

ANALYSIS (Professor J. W. Mallet).—One pint contains:

	Grain.
Carbonate of magnesia	0.085
Carbonate of iron	0.203
Carbonate of manganese	0.002
Carbonate of lime	0.055
Carbonate of ammonia	trace
Carbonate of lithia	trace
Chloride of sodium	0.005
Sulphate of potassa	0.014
Sulphate of soda	0.068
Sulphate of lime	0.013
Alumina	0.005
Silica	0.085
Organic matter	0.036
Loss	0.073
Total	0.644
	Cub. in.
Carbonic acid gas	0.77

THERAPEUTIC PROPERTIES.—This is said to be the best chalybeate spring in Virginia.

Rawley Springs are situated in Northwestern Virginia, on the southern side of North Mountain, amid beautiful scenery and salubrious air. *G. B. F.*

REACTION OF DEGENERATION. When a muscle is cut off from its centre of innervation it undergoes changes, among which is its susceptibility to the influence of electrical excitation. The alterations are known as *quantitative* and *qualitative,* with reference to the degree of contraction, and the variations in it respond to the interruption or closure of the current. Muscles which are paralyzed, there being total suspension of innervation, at the end usually of two weeks begin to undergo a change, when faradic (induced) currents produce no response, and the action under the galvanic current is reversed. The healthy muscle responds most vigorously to cathodal (negative) closure; while in well-established degeneration the anodal reactions of both kinds seem to cause the most lively contraction. In the unaffected muscle the healthy reaction would be as follows: *

$$\begin{array}{l} \text{Ca Cl C} > \text{An Cl C} \\ \text{Ca O C} < \text{An O C.} \end{array}$$

* The symbols used in the formulæ are the following:

D.R. = Degenerative Reaction.	Ca = Cathode.
An = Anode.	Cl (or S) = Closure.
O = Opening.	C = Strong contraction.
c = Medium contraction.	Tc = Tetanic contraction.
> = greater than.	< = less than.

As the process of degeneration advances we first find that the anodal closing contraction is equal to the cathodal closing, and that the anodal opening contraction is equal to the cathodal opening, but as the degeneration becomes confirmed we find the formula expressed:

$$\text{D.R.} = \text{An Cl C} > \text{Ca Cl C}; \ \text{An O C} < \text{Ca O C.}$$

Ultimately it is impossible to get any response whatever, except perhaps a weak anodal closing contraction. When such an advanced degree of degeneration exists the muscle undergoes atrophic changes, and its essential elements, more or less, disappear, while fatty deposit takes place. If the abolition of conductivity is not too extreme, or does not last too long, we find after a time an inverse restoration, the muscle responding feebly at first to an interrupted galvanic current of great strength, the normal reaction being finally attained, and afterward faradic excitability. For the electric diagnosis of the reaction of degeneration we should make use of a milliampère metre, and begin with a minimum current which may afterward be increased. If it requires a current of several milliampères to evolve a response, we may measure the qualitative improvement by the reduction in the required strength and note the same. Small carbon electrodes covered by absorbent cotton are the best. I have of late dispensed with cell selectors, and use simply a water rheostat and a milliampère metre.

Allan McLane Hamilton.

RECOARO, near Valdagno, in Venetia, is a pleasantly situated spa, lying in a sheltered valley at an elevation of about 1,500 feet above the sea. The climate is mild. There are ten or more springs in the place, the most important of which are the Lelia, Amara, Lergna, Giuliana, Civillina, and Virgiliana. The first four of these are the property of the government. The following is the analysis (made by Ragazzini) of two of these springs, computed in parts per thousand:

	Fonte Lelia.	Fonte Giuliana.
Calcium sulphate	1.310	trace
Calcium carbonate	1.016	0.100
Ferrous carbonate	0.069	0.063
Magnesium carbonate	0.099	0.051
Sodium sulphate	0.045	0.010
Magnesium sulphate	0.679	0.451
Magnesium chloride	0.004	0.003
Silicic acid	0.017	0.009
Organic matters, etc.	0.022	0.013
Total	3.261	0.700

The waters of Recoaro are given chiefly internally, though baths are also employed to a certain extent. They are recommended in the treatment of anæmia, in convalescence from typhoid fever and other debilitating diseases, in catarrhal troubles of the digestive and urinary systems, and in the visceral congestions following rebellious malarial fevers. The season extends from May to the middle of September. *T. L. S.*

RECTO-VAGINAL FISTULA. A communication between the rectum and vagina. In rare instances an opening is established between the vagina and some higher part of the intestine, oftenest the lower part of the ileum. A coil lying in the Douglas pouch may become adherent, and ulcerate or rupture into the vaginal cul-de-sac.

SYMPTOMS.—The escape of fæces and intestinal gases into the vagina and from the vulva. In some cases, when the edges of the fistula are ulcerated or cleanliness is neglected, vaginitis and vulvitis result. Then the patient suffers from itching, soreness, and offensive discharge. In sensitive natures this distressing infirmity induces depression of spirits, amounting sometimes to melancholia. The severity of the symptoms depends, however, on the size of the opening and the state of the bowels. If the opening be small, the diet properly regulated, and the parts kept clean, all the symptoms will be greatly mitigated.

CAUSES.—These may be classed under two heads—mechanical violence and disease.

Mechanical Violence.—All forms of difficult or instrumental labor in normal or deformed pelves; the use of forceps and the exercise of undue manual force; cephalotripsy; slipping of blunt hook, or other instrument used in the reduction of the size or extraction of the child; laceration by splinters of the bones of the fœtus. Contraction or other deformity of the bony pelvis, as from tumors, exostoses, and anchylosis of the coccyx; and a narrow or indistensible condition of the vagina, strongly predispose to this injury during labor. Certain operations, such as those for the relief of stenosis or atresia of the vagina; extirpation of tumors of the uterus or vaginal walls; excision of cancer of the rectum; and perforation of the rectum from rough or unskilful administration of enemata are occasional causes. Pessaries, when ill-fitting or neglected, sometimes ulcerate into the rectum, though much more rarely than into the bladder. Recto-vaginal fistulæ following labor are usually the result of lacerations; more rarely they result from prolonged pressure causing a slough with perforation.

Disease.—Cancerous, syphilitic, or other ulceration not rarely results in perforation of the recto-vaginal septum. Abscesses of the septum, from whatever cause, may rupture into both rectum and vagina. Suppuration of an adherent pelvic dermoid, or other ovarian tumor, or of an extra-uterine gestation-sac, may establish a fistula between rectum and vagina. The latter causes lead especially to the formation of fistulæ communicating with the upper part of the vagina.

Recto-vaginal fistula is very rare except in adults, but is not unknown even in infants. Bednar relates a case of gangrene of the recto-vaginal septum, resulting in fistula, in an infant of four weeks. This child died of cellulitis of the right arm. Witter relates another in a child of seven months, who had suffered from thrush for several months, when suddenly fæces began to escape from the vagina, and an ulcerated opening was found in the recto-vaginal septum. A healthy wet-nurse was procured, and with the addition of local cleanliness and the use of carbolized glycerine tampons to the vagina, the child recovered perfectly.

The course and duration depend on the cause and mode of origin, and the extent of the opening. A fistula from cancer usually grows larger, and there is no hope of cure. Syphilitic or other ulceration may heal and cicatrize partially, or even completely, and a spontaneous cure result. The latter result is probably rare in syphilitic ulceration, but more frequent in the simple forms. Perforating lacerations, and sloughing of the septum leading to fistula, in many cases get well by attention to cleanliness and by securing to the patient influences which improve general health. A few weeks may thus suffice to close a good-sized opening. Winckel saw an opening of the size of a dollar close in a fortnight. Spontaneous healing may be retarded or entirely prevented by cicatricial bands, which prevent the edges from coming together. Subsequent labors may result in enlargement of the opening, or in its closure, or leave it uninfluenced.

DIAGNOSIS.—This is usually a simple matter. Women suffering from the symptom called by German writers garrulitas vulvæ, in which air entering the vagina in certain positions, and escaping, it may be with noise, on changing position, or even without, during the movements of the pelvic floor synchronously with the movements of the diaphragm, are often in great distress of mind from imaginary fistula; but the gas thus escaping is odorless, being merely atmospheric air. The symptom is due to some defect of the forces which maintain intra-abdominal pressure. The accessibility of both vagina and rectum to examination by finger and eye through the speculum, renders diagnosis an easy matter. Except in the case of very small or remote fistulæ, examination by means of one finger in the vagina and another in the rectum, assisted it may be by probe or sound, at once discovers the opening. If very small, the speculum may be necessary. The injection of milk or some other colored liquid into the rectum will speedily reveal the opening in the vagina as the fluid escapes through it.

TREATMENT.—In cancer this is hopeless. In other forms of ulceration the first steps must be taken in the direction of securing cicatrization of the ulcer by the necessary constitutional and local measures. Until these measures have been tried operation is inadmissible. Recent lacerations, if discovered, must be immediately stitched, and the prospect of success is as good as in the immediate suture of lacerated perineum. If the lesion be not discovered in time, or if the primary operation fail, the parts on both sides of the opening, rectal and vaginal, must be kept clean, and stimulated if necessary, in the hope that spontaneous closure may result. This, we have seen, is by no means rare. In any case the size of the opening will certainly be much reduced. Vaginal tampons impregnated with glycerine and carbolic acid may assist. The bowels must be regulated, and accumulations of masses of hardened fæces in the rectum prevented. For the cure of chronic recto-vaginal, as for all other chronic fistulæ, two principal methods have been resorted to—cauterization, and suture after denudation.

Cauterization is comparatively easy of application, but very uncertain in its results. It is useless for large openings, and almost so for small ones, if the septum around the opening be thin. Most of the strong caustics, as well as the actual cautery, have been used. Solid nitrate of silver, nitric acid, and the acid pernitrate of mercury afford a list from which to choose. The whole extent of the fistula, from the vaginal to the rectal opening, must be cauterized. Dieffenbach's method was to cauterize a ring around the vaginal opening of the fistula with silver nitrate, and a few days later to apply the actual cautery to the vaginal opening and whole extent of the fistula. The galvano-cautery is better for this purpose than the Paquelin cautery, because it need not be heated till it is in contact with the surface to be cauterized. If the cautery fail after a trial or two, it is better not to repeat it, as the edges of the opening will be rendered cicatricial, and therefore in a less favorable condition for the success of the inevitable operation.

Denudation and Suture.—There are few cases which in skilled hands cannot be thus cured. More than one operation may be necessary, and in complicated cases various modifications of that suitable to simple cases may have to be resorted to. For the success of this, as of all plastic operations, it is essential that the general health be good and that the parts concerned be in a healthy condition. Two or three days immediately before the operation will be well spent in dieting and purging, especially with calomel and soda aided by salines. The diet had better consist of beef juice, well-boiled wheat flour porridge and milk, stale bread or toast, and, once a day, underdone tender mutton chops. Immediately before the operation both vagina and rectum must be thoroughly well washed out, and then irrigated with a 1 to 3,000 corrosive sublimate solution. The operation may be done through either vagina or rectum. The vagina is always selected when practicable, and the cases are very few in which it is not. The whole circumference and extent of the fistula should be freshened in such a way as to secure as broad surfaces as possible for apposition. This is to be done by making the opening funnel-shaped, the denuded surface at the vaginal opening being of greater extent than at the rectal opening. The rectal mucosa is to be interfered with as little as possible on account of its greater vascularity. The parts will be most effectually exposed for operation by placing the patient on her back and flexing the thighs on the pelvis, the anterior vaginal wall and labia being kept out of the way by retractors—those known as Simon's being the best. The direction of the line of sutures must be determined by approximating the edges with tenacula and observing that in which there is the least tension. Any cicatricial bands on the vaginal surface which prevent approximation must be freely divided, by knife or scissors, at some distance from the edges of the opening. The material of the suture may be fine silver or other sufficiently flexible metallic wire, carbolized silk, catgut, or silkworm gut.

Success may be attained by using any one of these, but most operators, probably, prefer silver wire, as it can so easily be secured by twisting in a cavity like the vagina. A variety of needles have been used, but the simplest appears to be Emmet's—a short, slightly curved needle held in the jaws of a needle-holder. It is threaded in such a way that a long loop of silk is made to draw the wire sutures into position. The needle is entered on the right or upper side (as the case may be) of the vaginal opening, at least half a centimetre ($\frac{3}{16}$ in.) from the denuded edge, and made to traverse the tissue of the septum and emerge just at the edge of the rectal mucosa. It is then carried across the opening to the other side, entered at the rectal edge, and brought out on the vaginal surface at the same distance from the edge of the freshened surface as on the opposite side. Five or six sutures to the inch will be necessary. The most exact coaptation possible of the raw surfaces must be secured, but the sutures must be drawn tightly enough to secure contact only, without strangulation. This last is the error most apt to be committed by inexperienced operators. The diet for the first three days should consist of animal broths, jellies, and gruels, with very little milk or other food which leaves a solid residue in the intestines. The bowels had better be allowed to remain undisturbed for three days, and then moved by a five-grain dose of calomel at bedtime, followed next morning by a saline laxative, such as a seidlitz powder, a teaspoonful of Epsom salts in a large glass of warm water, or a dose of Hunyadi or Friedrichshall mineral water. Soon after the saline is given, an enema of from two to four ounces of a warm solution of ox-gall must be cautiously thrown into the rectum. This will soften any hard masses which may have accumulated, and so prevent injury to the line of union during the evacuation. The bowels are to be moved every day, for at least a fortnight, by salines and the ox-gall enema. After the bowels have acted, some tender meat, bread, and light pudding may be added to the diet-list, but vegetables are to be withheld for a week longer. The sutures are to be allowed to remain for eight or ten days. The only objection to the method described, so generally successful, is that, if it fail, tissue has been removed, and this may prejudice the chances of success by subsequent operation. To obviate this objection various modifications have been practised. One is to dissect up a frill of vaginal mucosa in the form of a circle around the opening, and turn it into the rectum. The sutures are to be applied to both vaginal and rectal openings, the rectal ones being of catgut; or the edges of the fistula may be split, rectal and vaginal sutures being employed. When the fistula is low and near the sphincter ani, failure of the operation is more common than in the upper part of the septum. This is due to the disturbing action of the sphincter. In such cases success may be more certainly assured by dividing the whole of the tissues, sphincter muscle included, from the fistula, through the perineum, freshening the edges of the fistula, and then closing the wound as in the operation for complete laceration of the perineum. In certain other cases in which the recto-vaginal septum is very thin, the method of raising a flap of vaginal mucosa, sliding it over, and attaching it all round to the freshened edges of the opening, may be the best operation. *W. Gardner.*

RECTUM, MANUAL EXPLORATION OF THE. In 1872 Professor Simon, of Heidelberg, published, in the *Archiv für klin. Chir.*, an article "On the Artificial Dilatation of the Anus and Rectum for Exploration and Operation," in which he first described a method of exploring the lower bowel by the introduction of the entire hand. By this method of examination, he asserted that not only was he able to explore all of the pelvic organs, and to distinguish any pathological changes they might have undergone, but that the greater part of the abdominal cavity could also be reached. He further asserted that this method was so entirely free from danger that he had not hesitated to practise it on patients anæsthetized for other purposes. He thus describes the procedure: "The hand being well oiled, two fingers are at first introduced through the sphincter, then four, and finally the thumb and whole hand. The dilatation must be gradual, and assisted by a rotatory motion; and, if these directions be followed, a hand measuring twenty-five centimetres (nearly 10 in.) may be introduced absolutely without harm.

"The anus forms, in its greatest dilatation even—which is twenty-five centimetres in circumference or more—a narrow entrance to the larger cavity of the rectum. This cavity is formed by the inferior and middle portion of the rectum, the first of which lies outside of the peritoneum, and the second is covered only on the anterior portion by the posterior wall of Douglas' pouch, and extends to the superior third of the rectum, *i.e.*, to a point above which the peritoneum encloses the anterior and lateral walls of the bowel, and where it is attached to the os sacrum. This point lies from twelve to fourteen centimetres above the anus, and corresponds to the third sacral vertebra.

"The greatest width of the rectal cavity is at a point from six to seven centimetres above the anus, and its expanding capacity here is from twenty-five to thirty centimetres. From this point to the superior extremity of the middle third it gradually diminishes to from twenty to twenty-five centimetres, and from here it rapidly lessens until, in the middle of the upper third, it is not more than sixteen to eighteen centimetres in circumference, its narrowest portion being in the sigmoid flexure. The base of the thumb is thrust as far as to this point, twelve to fourteen centimetres above the anus, and half the hand can advance through the upper part of the rectum into the beginning of the sigmoid flexure. Therewith the abdomen can be palpated several centimetres above the umbilicus."

Simon thus limits the depth to which the hand should penetrate to the upper part of the rectum and lower part of the sigmoid flexure, and only claims to be able to palpate the abdomen somewhat above the umbilicus. Subsequent experimenters have not been satisfied with these limits, and have asserted that the hand could be made to enter the descending colon. This can readily be shown, on the cadaver, to be a physical impossibility. Nussbaum, in attempting to explore a supposed diaphragmatic hernia, reached the ensiform cartilage.

Later and more extended experience with this method has made it necessary to modify very materially the conclusions reached by its author. Many times disastrous consequences have followed its application, and not infrequently diseased conditions which were present have entirely escaped detection; we are forced, therefore, to the conclusion that it is necessarily attended with dangers which cannot be foreseen or guarded against, and that it is very much less successful as a method of exploration than was at first supposed.

This modification of opinion is manifested in late writers, who, like Koenig, admit the dangers and limit the method to very exceptional cases, or Follin ("Pathologie Externe," 1883), who speaks with reserve about the entire procedure. Furthermore, most of the general surgeries, and some of the special works on rectal diseases, ignore the subject entirely.

With the increased freedom with which exploratory laparotomy is now practised in the diagnosis of doubtful abdominal affections, the field for manual exploration by the rectum is certainly very materially limited.

The introduction of the hand into the rectum, even where the limits set by Simon were strictly observed, has been followed by incontinence of fæces, which, however, has generally disappeared in a few days. In other cases a fatal result has quickly ensued. The writer, some years ago, collected five fatal American cases, and the number since then has greatly increased. In the fatal cases the muscular coat of the bowel has alone been torn in some, and in others the peritoneal covering. In a case that came under my own observation the rupture of the peritoneal coat was evidently due to abnormal narrowing of the bowel from an abscess in the walls.

In one case an aneurism of the cœliac axis was found ruptured on the death of the patient, which occurred on the following day. In some cases the patients seem to have succumbed to shock.

In many cases this means of exploration unquestionably facilitates the exploration of the pelvic, and part of the abdominal, cavity.

Small tumors on the posterior aspect of the uterus have been discovered and their relations determined; the ovaries have been fully explored; the anterior surface of the sacrum has been examined and limited caries detected; and psoas abscess has been with certainty diagnosticated. The size of stone in the bladder, it is said, can be accurately mapped out, and stricture of the rectum has been explored.

But with so much success attesting the value of this means of exploration, it has not infrequently failed to discover stricture, even when as low down as the lower part of the sigmoid flexure, and has failed in the detection and attempted reduction of inguinal hernia. From the recorded experience of manual exploration of the rectum we can fairly conclude that its value has been exaggerated, and the dangers which attend it not duly appreciated; so that we feel justified in the conclusion that as a means of exploration it is allowable only in very exceptional cases. *N. P. Dandridge.*

REDRESSEMENT FORCÉ. A procedure introduced by Delore, of Lyons, in 1874, for the immediate correction of the deformity of knock-knee. His method is as follows: The patient, being anæsthetized, is placed upon the side, the deformed member resting with the trochanter upon the table, and the external malleolus raised about four inches above it. The surgeon now makes direct pressure in a vertical direction upon the affected knee, forcing it down by a series of jerks until the external condyle touches the table. A peculiar crackling is heard during the operation, which is caused by the giving way of the bony and fibrous tissues of the articulation. The acquired position is maintained by a starch bandage. The normal function of the joint is said to be restored at the end of about six months. A modification of this operation has been proposed by Tillaux, in which the limb is placed with the inner condyle resting upon the edge of the table, the thigh is steadied by an assistant, while the surgeon seizes the leg and forces it down until its axis corresponds with that of the femur. An instrument has been devised by Collin, similar in construction to the osteoclast, which effects the reposition of the deformed member by means of a long lever and the compound pulley. Redressement forcé is not an operation to be commended. It is a dangerous procedure, inflicting an amount of traumatism upon the joint that is liable to excite very intense inflammation, jeopardizing the utility of the limb, or even the life of the patient.

Thomas L. Stedman.

RED SULPHUR SPRINGS. *Location and Post-office,* Red Sulphur Springs, Monroe County, W. Va.

ACCESS.—By the Chesapeake & Ohio Railway (Newport News & Mississippi Valley Company) to Lowell, thence by stage to the springs, twelve miles. From the South by Norfolk & Western Railroad to Adairs, thence by stage.

ANALYSIS.—One gallon contains (Hayes):

	Grains.
Silicious earthy matter, containing traces of oxide of iron and ammonia, probably suspended merely..	0.70
Sulphate of soda, in a dry state (which forms with the water. 802 grains)	3.55
Sulphate of lime	0.47
Carbonate of lime (lime dissolved in carbonic acid)..	4.50
Carbonate of magnesia (magnesia dissolved in carbonic acid, and forming the "fluid magnesia")..	4.13
A peculiar substance, containing sulphur combined with organic matter	7.20
	20.55

Gaseous contents of a gallon, or 231 cubic inches:

Carbonic acid	5.750
Nitrogen	6.916
Oxygen	1.201
Hydro-sulphuric acid	0.397
	14.264

THERAPEUTIC PROPERTIES.—This water is remarkable as containing an "azotized base combined with sulphur," which Dr. Hayes pronounces new and peculiar. It is claimed that under this form the sulphur is readily absorbed. The reputation of this spring as a "cure" for pulmonary diseases antedates the recent treatment of tuberculosis by enemata of sulphuretted hydrogen, and there is good reason for believing that the water has often proven efficacious in those affections.

Red Sulphur Springs is situated in the southeastern portion of West Virginia, on Indian Creek. The ride from Lowell is through picturesque scenery and forests of pine, over an excellent road. The hotel, having accommodations for four hundred guests, is located in a valley thirteen hundred feet above sea-level. The property contains fourteen hundred acres, and possesses every variety of mountain scenery. There is excellent hunting and fishing in the surrounding forests and streams.

Geo. B. Fowler.

REFLEX ACTIONS, or **REFLEXES,** constitute a highly important and fundamental group of the phenomena displayed by animals, and although they are usually executed by muscular or epithelial tissues, and are oftenest observed in the form of motion or secretion, they are, nevertheless, wholly dependent for their peculiar characteristics upon the nervous system. Roughly speaking, they are distinguished by the fact that the immediate stimulus to the "action" lies outside the central nervous system, and yet, in a round-about way, works through it so that the nervous impulse or disturbance produced by the stimulus upon the periphery of the body, or elsewhere outside the central nervous system, travels first centripetally into that system, and then centrifugally out from it to the parts which finally execute the "action." The path described by the nervous impulse in its passage in and out resembles so plainly that described by the sound waves in an echo, or by a ray of light reflected from a mirror, as to suggest immediately the term *reflected*, or *Reflex actions*, or *Reflexes* for phenomena so peculiar and characteristic. But it cannot be too often repeated that this interesting analogy between the path of a nervous impulse in a reflex action and the path described by light, sound, etc., reflected from surfaces, is only an analogy; for while in the latter case the thing reflected is precisely like the thing impinging, and departs at definite angles, under rigid physical laws which are well understood, there is good reason to believe that the incoming nervous impulse in a reflex action of the animal body is unlike the outgoing impulse, which is certainly not merely a reflected portion of the former, but something different from, and often disproportionate to it, elaborated and sent forth by the central nervous system acting under the influence of the incoming impulse just received—doubtless in accordance with rigid physical laws, yet laws which are virtually unknown.

The parts of the mechanism involved are, primarily, the *stimulus* or *excitant*, which is the cause; and next, the sensitive end-organ (*a*) upon which the stimulus works until it has produced a nervous impulse (*b*), which travels along a nerve or nerve-fibre, the afferent or sensory nerve (*c*), by which the impulse is conveyed inward to the central nervous system—the brain or spinal cord. In a special portion of this central system (and oftenest in the spinal cord, which is in great part a special organ for this function), the impulse appears to be worked over in a reflex centre (*d*), from which after a time a new nervous impulse (*e*) is forwarded along another nerve or nerve-fibre, the efferent or motor nerve (*f*), which conducts the impulse to a nerve-ending or end-organ (*g*), which thereupon so stimulates the humbler muscular or epithelial tissues with which it is connected that these (*h*) execute the visible acts called reflexes. The whole group of events, from (*a*) to (*g*) inclusive, must, therefore, be regarded as in some sense the *effect*, of which the stimulus is the *cause*. Yet it should not be forgotten that this "effect" is largely influenced by other conditions, some of which will be mentioned hereafter. The ordinary observer, of course, witnesses only the beginning and the end of the action, although he may generally

perceive that considerable time has elapsed between the application of the stimulus and the reaction. This is known as the *reaction-time*, and that portion of it which is spent in the reflex centre (*d*) is known as the *reflex-time*.

Examples of reflex actions are abundant and familiar, as, for instance, the movements and laughter produced by tickling; coughing due to an irritated throat; vomiting from an irritant (stimulus) in the stomach, or a foreign body in the fauces. Light falling on the retina is the stimulus which leads to reflex movements of the iris, and (in many persons) to sudden sneezing. A finger unwittingly brought against a hot object, such as a stove, is almost instantly withdrawn, even without the help of volition. The legs of a decapitated frog, provided the spinal cord be still intact, are drawn away from acid or mechanical stimuli, and perform movements, almost purposeful in appearance, to wipe off bits of acidulated paper laid upon the flanks. The act of winking is a reflex mechanism, as are also the secretion of the digestive juices, some of the movements of the different portions of the digestive apparatus which convey the food to the rectum, the secretion of saliva, known as the "watering" of the mouth at the sight or smell of appetizing food, the flow of tears, the secretion of sweat from fear, etc.

Over against these REFLEX, or "reflected," actions must be put the AUTOMATIC actions of the animal body (such as volition, the beat of the heart, etc.), whose source is not immediately discoverable outside the central nervous system, or which arise within it. This division of nervous actions into the two great groups of "reflex" and "automatic" actions is the modern one. Before it was adopted physiologists maintained that many actions, such as eating and drinking, walking, talking, and the like, were purely voluntary; others, such as the beat of the heart, the peristaltic movement of the intestine, the flow of saliva and the other juices, the motions of the iris, etc., being purely involuntary; while still others, such as the respiratory movements (ordinarily done involuntarily, but capable of control to some extent, as when we sit with "bated breath"), winking, coughing, sneezing, etc., seemed to be of a mixed nature, being ordinarily free from the help or hindrance of the will, yet sometimes subject to its influence. This view was the one generally held in the last century, as, for example, by Dr. Robert Whytt, F.R.S., who, in the Introduction to his essay upon "The Vital and other Involuntary Motions of Animals" (1751), says: "Physiological writers have divided the motions of animals into voluntary, involuntary, and mixed. The voluntary motions are such as proceed from an immediate exertion of the active power of the will. The involuntary and mixed motions (which last, though subject to the power of the will, yet are not ordinarily directed by it) may be aptly enough comprehended under the general denomination of *spontaneous;* since they are performed by the several organs, as it were, of their own accord, and without any attention of the mind, or consciousness of an exertion of its power. Such are the motions of the heart, organs of respiration, stomach, intestines, etc., which have been also distinguished by the term *automatic;* though perhaps there is an impropriety in the word, as it may seem to convey the idea of a mere inanimate machine, producing such motions purely by virtue of its mechanical construction; a notion of the animal frame which ill agrees with the inertia and other known properties of matter."

As is foreshadowed in the latter portion of this quotation, the view stated in the former part has been somewhat changed since that time. The study of reflexes, which has been greatly extended along lines begun in part by Whytt, together with more exact studies of biology in general, and, especially, of the animal organism as an isolated mechanism acted upon by an environment external to itself, and by it reacted upon in its turn, have led to most interesting and fruitful conceptions of the physiology of the nervous system. Instead of voluntary, involuntary, and mixed actions, physiologists for the most part now agree to consider every action as aroused by some definite cause or stimulus. Stimuli proceeding directly from the environment, and provoking reactions upon it, plainly produce reflex actions. Stimuli arising within nerve-centres, and acting directly upon and through the centres in which they arise, produce automatic actions. Stimuli arising within the organism (it may be in nerve-centres), and acting upon nerve-centres other than their own, must clearly produce reflex actions, since the event differs essentially in nowise from an ordinary reflex action. If, for example, it could be shown that the heart-beat depends directly upon the pressure of blood upon the endocardium, or upon the quality of that blood, or upon any other stimulus affecting the cardiac ganglia from without, we should be forced to regard the heart-beat as a reflex act. But until some such evidence is forthcoming we are obliged to consider it automatic, self-regulating, spontaneous. In the same fashion, whenever it is proved beyond doubt that the activity of the respiratory centre depends wholly upon the oxygenation of the blood, we shall be obliged to regard it as a reflex centre; and there is a very considerable amount of evidence already pointing in that direction. Finally, it must not be overlooked that modern physiology, in using the word "automatic," or self-regulating, applied to a nerve-centre, does not regard automatic powers as either the result of chance, or as having arisen, by a kind of spontaneous generation, *de novo*. The powers and properties in any automatic centre to-day were either inherited (after having been acquired more or less remotely), or were acquired, being repeated until they became fixed in what we call habit. In the infant, talking is at first chiefly echo, imitation, and "reflexion," more or less perfect. Judgments, also, of distance, time, position, and the like, are chiefly the resultants of childish experience often repeated and blending with an inherited background, in which they grow and become more easily fixed or transformed into habits; and even actions apparently the most automatic or spontaneous, viz., those of the kind called voluntary, not seldom have their origin in remote impressions, or are directly modified by sensory impulses. Thus the acts of walking, talking, eating, etc., usually go on without the direct supervision of the will; and even the orator's words, chosen it may be beforehand, are delivered in a modified manner according to impulses arising from the picture of his audience upon his retina. Even the most characteristic beliefs, ideas, and desires of the most original minds are largely, if not almost wholly, the delayed or postponed resultants of earlier impressions acquired and inherited—reflexes infinitely elaborated and modified in the reflex or automatic centres, or having a very long "reaction-time."

Thus it appears that in comparison with complex automatic actions, ordinary reflex actions, which in their simplest forms are merely reactions upon an acting environment, are the simplest of all—the units, from the addition and multiplication of which we have reason to believe that the higher forms of action—automatic actions and even volition—are in great part compounded. That classification, therefore, of nervous actions into reflex and automatic, which is now almost universally adopted and to which we shall adhere, is evidently warranted more by convenience than by any marked fundamental differences between them.

GROWTH OF OUR KNOWLEDGE OF REFLEX ACTIONS.—The great body of facts relating to reflexes forbids an enumeration of all of them, but the more important principles thus far established and underlying their physiology, may be easily apprehended by reviewing the historical development of the subject. Here we are fortunate in being able to refer, even for the smallest details, to the work of Eckhard, whose extensive and laborious history of reflexes appeared in 1881. From this the following historical data have been chiefly, and often literally, taken (C. Eckhard: "Geschichte der Lehre der Reflexerscheinungen," *Beiträge zur Anatomie und Physiologie*, Band ix., Giessen, 1881).

Many reflexes had been observed, of course, long before any of them were understood. Sneezing, tickling, and coughing must have been always familiar to everybody. Moreover, it had not escaped notice that stimuli often

produce effects in parts remote from the point of application. Thus, "Hippocrates has observed that the unexpected sight of a serpent will make the countenance pale. The sight of grateful food occasions an uncommon flux of the saliva in an hungry person. When one eye is affected with an inflammation or a cataract, the other is often soon after attacked with the same disease. A bright light coming suddenly on the eyes sometimes occasions sneezing. We shut both eyelids, whether we will or no, as often as anything threatens to hurt either eye. The contraction of the pupil is not owing to light acting as a stimulus on the iris, but solely to the sympathy between this membrane and the retina." This quotation from the "Works of Robert Whytt, M.D.," Edinburgh, 1768, p. 495, indicates well some of the reflex actions which were then familiar, and also (in the last sentence) introduces us to the then prevailing theory of *physiological sympathy*, which was the forerunner of the modern doctrine of reflex actions. To Whytt belongs in large measure the honor of showing that "sympathies" are effected through the central nervous system; and that he held very advanced views appears, *e.g.*, from the following: "Cold water thrown on any part of the body that is warm produces a sudden contraction of the whole vessels and pores of the skin. . . By doleful stories or shocking sights delicate people have been often affected with fainting, etc., and, although in these cases the changes produced in the body are owing to the passions of the mind; yet, as the mind is only affected through the intervention of the optic and auditory nerves, they seem proper enough instances of the general sympathy that extends through the whole nervous system" (*loc. cit.*). Much, however, had been learned long before the time of Whytt. Hippocrates has been quoted already, as having noted the blanching of the face from fear, etc. Galen was aware that closure of one eye causes the pupil of the other to dilate, although he did not know of any other motions of the pupil, and attributed this "dilatation of the pupil of the open eye to its having the spirits which used to be bestowed on both eyes now determined into it alone" (*loc. cit.*). Explanations like this were to be expected before the discovery of the circulation of the blood, or the establishment of the fact that the arteries are not air-tubes. In fact, we learn from Whytt that at the beginning of the sixteenth century "Achillinus makes particular mention of the motion of the pupil from different degrees of light; which, however, was so little attended to that its first discovery has been generally ascribed to Father Paul, who lived about a hundred years after him. However, neither Father Paul nor Fabricius ab Aquapendente seems to have known how these motions are performed" ("Whytt's Works," p. 61).

With the seventeenth century a change began, although theories and arguments rather than proofs still held the day. Among the authors of that time Descartes comes first. He dwells upon the subject in two separate papers, viz., "Les Passions de l'âme" (1649), and "Tractatus de Homine" (1677). In the former he points out that involuntary movements may be evoked, without affecting consciousness, by the most unlike sensory nerves and the brain; this, too, in some groups of muscles rather than in others. As an example, he cites the involuntary shutting of the eyelids, and other movements which we unconsciously and involuntarily make for defence from threatened danger. It is interesting to learn, moreover, that he considers as the central organ, or seat of transfer of sensory to motor impulses—not the brain or spinal cord, but—the pineal gland, long regarded as the seat of the soul, but now known to be non-nervous in nature, made up of a mesh of blood-vessels, and probably representing the rudiment of a third, unpaired, and median eye. In this connection Descartes spoke of the impulse as "reflected." The second paper is interesting chiefly because it shows Descartes' clear comprehension that these events occur without the participation of the "soul."

Swammerdam, in his "Bibel der Natur" (1652), refers to the involuntary movements which men and the lower animals, especially when sleeping, exhibit whenever their skins are gently irritated; and says that they occur without any great participation of the will, yet attempts no explanations. Willis, on the other hand, in 1664, was not only familiar with many genuine reflex phenomena, but gave of them explanations similar to those given today. He mentions the involuntary placing of the ears, the involuntary cries, etc., of animals to which auditory impulses come, and compares the whole event in each case to an "echo." Willis regarded the brain as the "centre" of such physiological echoes, although he believed that the transfer of the impulse from the sensory to the motor nerves takes place also through peripheral anastomoses.

In the seventeenth century experiments upon decapitated animals were also known, and although explained otherwise than they are to-day, and not brought into line with the observations just recorded, they are of great interest as being the earliest examples in experimental physiology which prove that *in brainless animals movements can be evoked by stimuli.* Toward the end of the century physiologists generally seem to have been familiar with such observation as that of Boyle, described by himself as follows: "The body of vipers may be sometimes, two or three days after the skin, heart, and head, and all the entrails are separated from it, seen to move in a twining or wriggling manner, nay, may appear to be manifestly sensible of punctures, being put into a fresh and vivid motion when it lay still upon being pricked, especially on the spine or marrow, with a pin or needle." Yet it was only in the next century that physiologists pushed the analysis further. At this time they had, however, established the important fact that beyond the domain of a will conditioned by the presence of the brain, there must exist somewhere in the body a source of orderly muscular movement.

The question whether or not these movements are accompanied by consciousness does not seem to have attracted much attention as yet, although, as we shall see, it afterward assumed great prominence. Some, indeed, like Boyle, recognized the two possibilities, viz.: first, that the sensorium reaches down into the spinal cord, so that the latter is conscious by itself alone, as well as when joined normally to the brain; or, second, that all parts of the body may be potentially conscious or "independently perceptive," consciousness being diffused throughout the body, and not confined strictly to the brain, or brain and spinal cord. An experiment which we now know to be misleading, seemed to point to the first explanation. It was observed that decapitated frogs do not merely pull back their legs on being irritated, but also crawl and leap in a manner closely resembling the normal. This is indeed true in some cases, especially if the decapitation is done by scissors, one blade of which is put in the back of the mouth—in which case the optic lobes are generally only partially, if at all, removed—or if any large portion of the medulla be left connected with the cord. But if the *whole* brain, including the medulla oblongata (which was then usually reckoned as a part of the spinal cord), be taken away, the crawling or leaping movements never appear. The frog squats flat upon the belly, and is unable to do other than simple, purely reflex, movements.

In the eighteenth century more rapid progress was made. The chief place of "transfer" (*Uebertragung*) of the sensory to the motor nerve, or, as we will henceforth designate it, "the central reflex organ," was finally settled, after much debate and experimentation, which constantly brought new facts to light. Regarding the central reflex organ (which, as has been insisted above, is not a mere shunt or reflecting organ (p. 151), two hypotheses had arisen, viz.: first, the suggestion of Willis, that the peripheral anastomoses and sporadic ganglia are such reflex centres; and, second, that the brain and spinal cord (central nervous system, often called the *sensorium commune*) are the great central reflex organ—an idea held earlier by Descartes, etc. Of the first theory Vieussens was the principal supporter, although around him were grouped H. Boerhaave, Comparetti, Bergen, Walther, Vater, Buchner, Meckel, Gasser, Camper, and others,

chiefly anatomists. The only ground for this theory of the peripheral anastomoses lay in the argument (*post hoc ergo propter hoc*) that in the parts which stand in sympathy peripheral anastomoses occur in the nerves there distributed. Tissot ("Traité des nerfs et de leurs maladies," tome ii., pt. ii., Paris, 1780) has given a number of examples of this kind. The theory that the central nervous system is also the central reflex organ was defended by Perrault, Astruc, K. Boerhaave, Haller, Van Swieten, Monro, Marherr, Thaer, La Roche, Whytt, Tissot, and others; of whom Astruc, K. Boerhaave, and Whytt brought forward the most effective evidence for the theory and against that of the peripheral anastomoses. Astruc and K. Boerhaave affirmed (1) that there are sympathies where no anastomoses exist to regulate them; and (2) that even where there are anastomoses there is no genuine fusion of the nerve-fibres, which run parallel to one another into the central nervous system, and do not unite in the anastomoses, thus making "sympathy" in the latter impossible. It is not clear whether these bold (and certainly prophetic) statements were mere guesses, or based upon actual observation. Both these authors employ the word "reflexion," but not, as Cayrade would have it, for the first time. It had been used already by Descartes and Willis.

Most significant and fruitful of all was the work of Robert Whytt, to whom reference has been made above. Of him Eckhard well says: "R. Whytt is, in manifold ways, noteworthy in the history of reflex actions. We may grant that his conceptions of them were not exactly like our own, and yet find in his works a wealth of experimental discovery to which his predecessors did not approach in the remotest degree; containing in their infancy many principles of the physiology of reflexes which have only lately become the subjects of extensive research; besides a much more fundamental refutation of the 'peripheral anastomosis' theory than had been given by Astruc or anyone else; and finally, and perhaps most important of all, the first *experimental* evidence that the reflex movements of decapitated frogs are governed and elaborated by the spinal cord."

The more important discoveries of Whytt ("The Works of Robert Whytt, M.D.," etc. Published by his son. Edinburgh, 1768) may be summarized as follows: 1. It was known that decapitated animals exhibit movements upon being duly stimulated; it was suspected, urged, believed, and denied that the spinal cord is the central reflex organ, the seat of transfer of the impulse from the sensory to the motor nerve. Whytt *proved* that the *spinal cord* is the essential centre in such cases, by the simple but conclusive experiment of destroying it and then observing that movements afterward never ensue. Moreover, he frankly owns that the experiment was not wholly original with him, but done after the method of Dr. Stephen Hales, who, it will be remembered, was the first to take the blood-pressure by the manometer, and whose works on "Staticks" abundantly prove his ingenuity. "The late reverend and learned Dr. Hales informed me that, having many years since tied a ligature about the neck of a frog to prevent an effusion of blood, he cut off its head, and, thirty hours after, observed the blood circulating freely in the web of the foot; the frog also at this time moved its body when stimulated; but that, on thrusting a needle down the spinal marrow, the animal was strongly convulsed and immediately after became motionless" (*l. c.*, p. 290. See, also, pp. 284, 510).

2. Whytt was the first to point out that after decapitation the movements which are afterward easily evoked in such animals cannot be obtained till after the lapse of a few minutes. This is probably the first scientific observation of *inhibition*, and to it he added others (pp. 303, 501–502).

3. Whytt distinguished more clearly than had been done before him certain actions as reflex, the clear explanation of which was novel. We have mentioned above his reference to the "watering" of the mouth at the sight of "grateful food." This, of course, opened up the whole subject of reflex secretions. His theory of the reflex dilatation and contraction of the pupil is also noteworthy. "The pupil is contracted more or less in proportion to the quantity of light admitted into the eye, not on account of any immediate action of this subtile fluid on the fibres of the iris, as some have imagined, but in consequence of its affecting the tender retina with an uneasy sensation" (p. 62). "The contraction of the pupil when light offends the eyes, and of the eyelids when grosser bodies threaten to hurt them; . . . the copious secretion of tears and the saliva when stimulating substances are applied to the eyes or taken into the mouth. . . . These motions cannot, in my opinion, be referred to any connection or communication among the nerves, but to the brain itself" ("On the Sympathy of the Nerves," *l. c.*, p. 519).

It has been vigorously urged that Prochaska (1749–1820) is entitled to be regarded as the principal founder of the modern doctrines of reflex actions; but, in spite of the conflicting testimony, if we observe carefully the ideas, knowledge, and discoveries of Robert Whytt, we shall not greatly err, if we hold with Eckhard "that, aside from some few observations, Prochaska has neither discovered new facts or explained old ones, nor to any great extent advanced the theories of reflex actions" (*cf.* "Unzer and Prochaska on the Nervous System," Sydenham Society, London, 1851, esp. pp. 429–438).

Herbert Mayow showed, in 1823, more clearly than had been shown hitherto, that the reflex movements of the pupil depend primarily on stimulation of the optic nerve, and that the experiments succeed (in pigeons, with which he worked) even after decapitation, provided that the forepart of the crura cerebri, corpora quadrigemina, and the second and third pairs of cranial nerves are unharmed. This was perhaps the first experimental evidence of reflexes in heads separated from the rest of the body, and in the brain alone (*cf.* Herbert Mayow's "Commentaries on Physiology," ii., London, 1823).

The most prolific writer upon, and vigorous exponent of, the doctrine of reflexes that the nineteenth century has produced is undoubtedly Marshall Hall; and yet a comparison of his labors with those of his predecessors and followers, inclines us to agree with Eckhard, that it is very likely true that Marshall Hall made his first discoveries, and formed his earlier theories independently, and in ignorance of the work already done. Finding himself thereafter with a reputation to sustain, and differing somewhat from the older authors, he published copiously (perhaps rather than wisely), and without always giving full credit to his predecessors. Nevertheless, his services are very great and conspicuous, and his publications, reaching from 1832 to 1847, drew general attention to, and aroused great interest in, the whole subject. Hall was the first (unless Johannes Müller be excepted) to observe the rise of reflex irritability under opium and strychnine, and the fall under prussic acid; the first to observe the interesting fact that reflexes are more easily evoked through nerve-endings than nerve-trunks; the dependence of tonus upon the spinal cord, etc. He also proposed the hypothesis of a special "excito-motor system" distinct from the sensory-motor; the former to account for reflexes free from consciousness, and concerned chiefly with the spinal cord; the latter to explain the ordinary actions consequent upon sensation and volition. The hypothesis called for a double set of nerve-fibres going to all parts of the skin, but ending centrally, the one in the cord, the other in the brain.

Grainger sought to find an anatomical basis for this theory of Hall, and in his "Observations on the Structure and Functions of the Spinal Cord" (London, 1837), he claimed to have observed that, from the anterior and posterior roots of the nerves certain small threads proceed to the gray substance, while others enter the white substance of the cord, and then pass upward; accordingly, he assumed the former to be the "excito-motor;" the latter, those of sensation, perception, and voluntary movement. From the present standpoint of physiology it is interesting to perceive that, even so early as this, Grainger was led to conceive the gray substance of the

cord to be, in the last analysis, the principal central reflex organ within which the exchange from afferent to efferent impulses is effected. Grainger appears also to have been the first to formulate definitely the theory of the reflex function of the submaxillary ganglion in the act of salivary secretion; in which the afferent twigs are supposed to belong to the lingual, and the efferent to be branches (chiefly of the *chorda tympani*) from the ganglion. It was not new to regard the sporadic ganglia as reflex centres, however, for that was involved in the "anastomosis" theory. Indeed, Prochaska regarded the sympathetic ganglia as important reflex centres, and Le Gros Clark, a year earlier than Grainger, had done likewise. It is interesting to remark here that, as we shall see hereafter (p. 156), Claude Bernard, more than a score of years after Grainger, and, apparently, quite independently, took almost exactly the same ground regarding the function of the submaxillary ganglion, and adduced important experimental evidence which led to fresh researches, and to one of the most animated and fruitful debates in the history of experimental physiology.

Johannes Müller was working upon reflex actions at the same time as Marshall Hall, and in the first edition of his "Text-book of Physiology" (1833), gives the principal results of his labors. Unlike Hall, he was well acquainted with the history of the subject, although he seems to have overlooked the fact that the Hales-Whytt fundamental experiment had been repeatedly done already, and, like Hall, "discovered" it once more, apparently quite independently. He makes the usual statements about reflexes, gives the usual examples, and discusses thoroughly the sporadic ganglion question. In this he inclines to the belief that sporadic ganglia do not behave as reflex centres, but pronounces the question unsettled.

In 1833 Ehrenberg first published an account of the ganglion cells (in the sympathetic ganglia, and possibly in the cortex of the brain), (*Pogg. Ann.*, Bd. xxviii., 1833, p. 449). In 1837 Purkinje described them more clearly, in the brain and spinal cord, noting their processes or "poles," but not observing any connection of these with the nerve-fibres. Valentin, in 1839, proposed the hypothesis that these ganglion cells effect the transfer (*Uebertragung*) of the impulses in reflex actions, and are therefore the ultimate reflex centres. In 1846 R. Wagner and Robin (Wagner's Physiologie, Bd. iii., 2, 361) saw the ganglionic processes in direct connection with nerve-fibres, and Wagner suggested that the transfer is by a virtually continuous path—the three principal elements being the afferent nerve, the centre, and the efferent nerve.

From the time of Marshall Hall up to the present day so many workers have been engaged upon the physiology of reflex actions, that it is here impossible to do more than, with Eckhard, to follow out some of the lines of inquiry which seem most interesting, viz.:

1. The Methods of Study.
2. The Nervous Mechanism of Reflexes.
3. Inhibition of Reflexes.
4. The Time-Element.
5. The Effects of Drugs, Temperature, etc., upon Reflex Actions.
6. Laws of the Propagation of Reflexes.
7. Reflex Centres.

Methods of Study.—In passing from qualitative to quantitative studies of reflexes, it becomes necessary to measure and compare stimuli as causes, and actions as effects. The stimulus remaining the same, it has been found that the excitability of the reflex-apparatus varies with different circumstances, such as temperature, moisture, drugs, and, above all, the condition of the spinal cord. Or the apparatus being the same, different stimuli produce different effects.

The first successful attempt to secure precise results was by means of *chemical stimulation*, in a way since known as "Türck's Method" (Ludwig Türck, "Ueber den Zustand der Sensibilität nach theilweiser Trennung des Rückenmarks," *Zeitschrift der k. k. Gesellschaft der Aerzte zu Wien*, vii. (1851), 189). Türck's method consists in allowing the toes of a suspended frog to dip to a fixed depth in very dilute sulphuric acid. The time which elapses between the immersion of the toes and the pulling of them out by the animal—the *reaction-time*—is then taken as the measure of the excitability of the reflex apparatus. Türck used acid of one-fifth to four-fifths per cent., and found that in any one animal, the conditions remaining the same, the reaction-times are equal, especially if care be taken to wash off the acid promptly after the dipping of the foot. Setschenow added a useful feature to the method by introducing the metronome as a simple and convenient chronograph, and he, besides others, has employed the method without questioning its accuracy. Some, however, have alleged that with very great dilution of the acid frogs react only after longer and longer intervals. Still others maintain that the first reaction follows later (*i.e.*, after a greater interval) than in the succeeding trials. These and other disputed points in Türck's method have been carefully investigated by W. Baxt (*Berichte der König. Sächs. Gesellschaft d. Wiss.*, 1874, pp. 309–314).

According to Eckhard (*Beiträge*, etc., ix.), who has thoroughly reviewed the literature of the subject, three important considerations must be borne in mind, not only in this method of chemical stimulation, but in thermal and other methods described further on, viz.:

1. Very gradual increments of strength in an ineffective irritant will not always suffice to produce a reaction, even though they be continued until a greater strength has been reached than—otherwise applied—would prove to be a powerful stimulus; for it has been shown, especially by C. Fratscher (*Jenaische Zeitschrift*, N. F., ii., 1875, 30), that if we begin to stimulate by a solution of acid, alkali, etc., so dilute that no reaction follows, we may *gradually* increase its strength up to a point where actual destruction of tissue ensues, without once evoking a reaction. With hot water equally astonishing results were obtained, for Fratscher found it possible to heat slowly, not only decapitated, but even normal, frogs from the ordinary temperature until they passed into *caloris rigor*, without any reflex actions ensuing at any point of the process.

2. The reaction-time varies with the strength of the stimulus. In general, acids of the strength of the acids of the body, such as that of the gastric juice, are ineffective. Above this point, according to Baxt, while the concentration increases arithmetically, the reaction-times diminish geometrically.

3. For each individual there is a point where stimuli of a certain weakness will evoke (though barely) a reflex action. These stimuli are called *minimal stimuli*, and the point itself is called the *Reflexschwelle* or *reflex threshold*. If we overstep this threshold by still greater dilution of the irritant, no reaction follows; if we have been using ineffective stimuli, this marks the lowest point at which reaction begins.

Mechanical stimulation is probably the oldest, and yet the least trustworthy, method of evoking reflexes. The difficulty of making quantitative measurements by its means is, however, so great as to make other methods preferable. Here, also, increments of stimulation must be sudden and considerable, for it has been found possible even to crush a limb without ever provoking action, provided care be taken to make the increments of pressure small and gradual.

Thermal Stimulation.—Here too, as has been shown above, gradual increments are ineffective to evoke reaction. Heinzmann (*Pflüger's Archiv*, vi., 1872, 222 found that the increments, when a whole leg was immersed, must exceed $\frac{1}{250}$ to $\frac{1}{300}$° C. per second, otherwise the animal might pass motionless into *rigor caloris*. Foster (*Journal of Anat. and Physiology*, vol. viii., p. 45) found that if only the toes were immersed, it was impossible to pass, however slowly, above 35° C. without reaction; and explained the fact of easier reaction following the immersion of a smaller area by comparing it to the easier stimulation of a nerve through a bit of skin than through the whole nerve-trunk. Fratscher, however, finds it

possible to go higher than 35°; indeed, as high as is desired even with the smaller area. It has been suggested by Sedgwick (*Studies from Biol. Lab. Johns Hopkins Univ.*, ii., 385) that the greater difficulty of arousing reflexes by thermal stimuli, when larger areas are immersed, is due not so much to the stimulation of a large area as to the heating of the whole animal by the circulating blood to such an extent that the contrast between the part in the water and that out of it never amounts to enough to constitute a stimulus. That this is very likely true is shown by stopping the circulation at the beginning of an experiment; after which it is found that comparatively low temperatures produce movements, even when large areas are immersed.

The question has been raised whether the reflexes produced by various stimuli are produced through the same end-organs. Türck, who first introduced the subject, takes the affirmative. Setschenow (Setschenow und Paschutin, "Neue Versuche," etc. Berlin, 1865), and Danilewsky (*Archiv für Anat. und Physiologie*, 1866, p. 677) take the negative, the latter holding that a difference exists between "tactile" and "pathic" reflexes. The subject cannot be further treated here, but it may suffice to say that the present tendency appears to be toward the idea of a (limited) number of end-organs, rather than of one kind susceptible to all sorts of stimuli.

Electrical Stimulation.—The same general statements may be made here as in the other cases of stimulation. The constant current is effective only when of a certain strength; but summation may occur and give rise to stimulation, in the use of streams so weak as to be ineffective, by making the current interrupted. Induced currents at rather long intervals may be of considerable strength, and yet produce no reactions; while weaker but more frequent currents may be "summated" and produce reactions. This whole subject has been accurately studied by Stirling ("Berichte der Königl. Sächs. Gesellschaft der Wissenschaften," 1874, p. 372), who carried out his investigations in Ludwig's laboratory, and employed novel and exact apparatus. Reference must be made to his complete paper for the details.

THE NERVOUS MECHANISM OF REFLEXES.—Since the time of Mayow, Hall, Müller, and Grainger (*vide supra*), there has never been any doubt that the brain acts as a central reflex organ. It does not appear to act as a whole, but the cerebrum and cerebellum seem rather each to include many centres. The spinal cord, however, is the central reflex organ *par excellence*, not so much from the great number of reflex centres located in it (for it must be remembered that the extreme hind-brain—the *medulla oblongata*—is very rich in reflex centres), as from the fact that this is probably its most important function, while the brain, including the medulla, is much devoted to other important functions. It must not be forgotten, however, that the hindmost portion of the spinal cord does not act as a central reflex organ, as was first shown by Volkmann (Müller's Archiv, 1838, p. 15; 1841, p. 354), and has since been confirmed. Thus Sanders-Ezn (1867) affirms that no reflexes can be obtained from the cord of a frog behind the level of the eighth pair of spinal nerves. Koschewnikoff states that all reflexes cease upon removal of the cord as far back as the middle of the fifth vertebra. Eckhard finds that even strychnized frogs showed no reflexes with the hindmost portions only of the spinal cord intact.

It is no longer held by anyone that reflexes occur according to the old doctrine of the peripheral anastomoses. When, however, we turn to the question whether or not the sporadic ganglia can serve as reflex centres, we find a mass of conflicting testimony, and great difference of opinion. It may be said, meanwhile, that although the possibility that they may so act is granted, no sufficient proof has yet been given that they do or do not. At the same time it cannot be denied that if they do act as reflex centres some evidence of the fact ought to be easily obtained; and, on the other hand, it is not difficult to see the advantages which must accrue to that organism whose central government is instantly and directly informed of changes occurring in its periphery. It is much easier on *à priori* grounds to suppose internal, and, so to speak, domestic affairs, such as the heart-beat, vaso-motor actions, and the like, to be partially self-controlled, automatic, or even purely reflex, than more external affairs, such as locomotion, motion, secretion, etc., which are far more irregular and unequal. In the latter the advantage of a central co-ordinating apparatus in direct communication with every part of the body is too evident for debate. That this central system should reserve direct reflex authority over the periphery, and surrender to internal machinery the general control of vaso-motor actions, etc., is also quite within the limits of possibility.

Studies of the reflex powers of sporadic ganglia have been made upon the cardiac ganglia, the inferior mesenteric, and the submaxillary ganglion, all of which are macroscopic, besides the microscopic ganglia of the blood-vessels, etc., either known or supposed to exist. Most famous of all is the controversy of which the reflex functions of the submaxillary ganglion form the subject. This ganglion, from its size, its accessibility upon the living animal, and from the ease with which its effects upon salivary secretion can be estimated, is well adapted for use as a "test case." It is connected with the submaxillary gland by the chorda tympani, with the tongue by the lingual, and with the brain by both.

The debate was begun by Claude Bernard (*Comptes Rendus*, 1862, ii., 341), who seems to have overlooked the earlier experiments of Grainger (see above), and was taken up by Kühne (*Lehrbuch der Physiol. Chem.*, 1868, p. 3) and Vulpian (*Leçons sur l'app. vaso-moteur*, i., 311, 1875), who supported Bernard, and by Eckhard (*Zeitschrift für ration. Med.*, xxix., 74), Heidenhain (*Breslau Studien*, 1868), Bidder (*Archiv für Anat. und Physiol.*, 1867, 1), and Schiff (*Moleschott's Untersuchungen*, x., 1870, p. 423), who opposed him in the theory that the submaxillary ganglion acts as a reflex centre for salivary secretion. This celebrated discussion, so important to the student of the physiology of reflex actions, has been admirably reviewed and summed up by Dr. Michael Foster in his well-known "Text-book of Physiology," where he treats of the physiology of secretion in general, and then proceeds as follows:

"In the angle between the lingual and the chorda tympani, where the latter leaves the former to pass to the gland, lies the small submaxillary ganglion, from which branches pass to the lingual on the one hand, and to the chorda on the other; branches may also be traced toward the ducts and glands, and toward the tongue. It has been much debated whether this ganglion can act as a centre of reflex action.

"Bernard found that after he had divided the conjoined lingual and chorda at about one centimetre above the place where the chorda diverges to the gland, stimulation of the lingual at about three or four centimetres distance below the ganglion still caused a flow of saliva; this effect, however, was no longer seen when the branches passing from the ganglion to the lingual had been previously divided. He explained the result by supposing that the impulses generated by the stimulus were conveyed by afferent fibres in the lingual, along the lingual roots of the ganglion, to the ganglion, and were thence reflected by efferent fibres along the branches from the ganglion to the chorda, and so to the gland. The ganglion, in fact, acted as a reflex centre. The same apparent reflex secretion could also be induced, but less readily, by pinching the peripheral branches of the lingual near the tongue, or by dipping them into concentrated salt solution. In this case also the secretion failed to appear if the lingual roots of the ganglion were divided. Such a reflex secretion was very difficult to obtain by stimulating the mucous membrane of the tongue; but Bernard was successful when he stimulated the tongue directly with a galvanic current, or drew the tongue out and placed ether on its surface. The secretion in all these cases was accompanied by a dilatation of the blood-vessels of the gland, and the effect on the gland was indeed wholly similar to that of directly stimulating the chorda. Bernard further insisted that in these experiments no anæsthetics were to be used, and observed that

the reflex act was no longer visible when two or three days had elapsed after section of the conjoined lingual and chorda trunks. Both these facts rather militate against his view, since it seems improbable that a sporadic ganglion should be so susceptible of anæsthetics, or that degeneration and functional incapacity of the ganglion should follow upon section of the conjoined lingual and chorda, so long as the afferent and efferent connections of the ganglion with the gland and tongue were kept up.

"Eckhard, in repeating Bernard's experiments, failed to obtain any effect from dipping the endings of the lingual nerve in salt solution, or from placing ether upon the tongue, and he very naturally argued (being supported in this by Heidenhain) that the effects seen when galvanic stimulation was employed were due to an escape of the current upon the chorda fibres. Schiff did obtain reflex secretion, after section of the conjoined lingual and chorda, by direct galvanic stimulation of the tongue, and by pouring ether on the surface of that organ; but the currents necessary in the first case to produce any effect were so strong that escape must have taken place, and in the second case the secretion appeared even though the lingual was divided close under the tongue, and when, therefore, this nerve could not have been the channel for conveying impulses to the submaxillary ganglion. He further pointed out that in large dogs, at all events, certain fibres of the chorda, after running along the conjoined lingual and chorda, do not leave the lingual with the rest of the fibres going straight to the gland, but continue in the lingual close up to the tongue, then bend round, and, as recurrent fibres, run back and eventually join the nerve going to the gland. He in consequence argued that Bernard, in stimulating the lingual below the divergence of the chorda, was in reality stimulating not afferent but efferent fibres. But in such a case these recurrent fibres must pass to the chorda through the ganglion, if Bernard's result be true that the reflex effect ceases when the lingual roots of the ganglion are divided. Schiff further states that these recurrent fibres degenerate in the retrograde portion of their course when the lingual is divided near the tongue, and that no effect follows upon stimulation of the lingual if the lingual have, some five or six days previously, been divided close to the tongue, so as to cause degeneration of the recurrent fibres; provided that the stimulation be not so strong as to lead to an escape of the current to the main chorda fibres. In small dogs Schiff could not so readily demonstrate these recurrent fibres, and though he says the apparent reflex secretion is more easily obtained in large dogs, such as Bernard probably used, than in smaller ones, it is improbable that mere size should make such a difference in nervous distribution; and if an escape of current can explain the results in the one case, it can also, probably, in the other.

"Bidder's account of the nerves of the ganglion at first sight offers support to Bernard's views. In the dog he finds, passing from the ganglion direct to the tongue, medullated nerve-fibres which do not degenerate when the chorda is divided at its exit from the skull. These fibres, accordingly, would seem to take their origin in the ganglion, and to be the afferent nerves required for Bernard's views. When Bidder divided the conjoined lingual and chorda he found fibres, the chorda fibres, after about three weeks, completely degenerated; not only those forming the nerve going to the gland, but also those constituting the branches going to the ganglion, *i.e.*, the chorda roots of the ganglion. In the ganglion and in the branches going from the ganglion to the gland were seen numerous degenerated fibres in the midst of undegenerated (but non-medullated) fibres which seemed to have their origin in the ganglion itself. Thus, after complete degeneration of the true chorda fibres, there still remained intact (1) the ganglion, (2) fibres from the ganglion to the tongue, and (3) fibres from the ganglion to the gland; in fact, exactly the nervous mechanism demanded by Bernard's view. But Bidder, like Eckhard, failed to obtain a reflex secretion by pouring ether on the tongue after division of the conjoined lingual and chorda, and he found that galvanic stimulation of the nerves going from the ganglion to the tongue was of no effect, provided that errors due to escape of current on to the main chorda fibres were avoided by previously inducing, through section, degeneration of the chorda fibres, including the chorda roots of the ganglion. So that Bidder's results in the end oppose the view that the ganglion can act as a centre of reflex action. In fact, such a view must be regarded at present as not proven."

For the discussion of cardiac and other vaso-motor ganglia, etc., as reflex centres, the discussion of which belongs rather to the physiology of automatic actions, reference must be made to the original paper of Eckhard (*Beiträge zur Anat. und Physiol.*, ix.), where, also, the literature may be found *in extenso*.

Inhibition of Reflexes.—The actions of the animal body may be physiologically interrupted, postponed, or otherwise modified. Such interruption or postponement is called *inhibition*, of which the most striking example, perhaps, is the slowing or total stoppage of the automatic heart-beat by stimulation of the pneumogastric nerve. More familiar examples are the voluntary refusal to be tickled, or to sneeze, or to cough when only a strong effort of the will forbids what would otherwise happen; the frequent insensibility to pain when greater pain is being suffered; and the unsusceptibility to many stimuli, ordinarily effective (absent-mindedness or preoccupation), induced by "absorbing" pursuits of work or play. All these phenomena, and more, were well known when, in 1863, Dr. J. Setschenow, professor of physiology in St. Petersburg, published a work upon inhibition ("Physiologische Studien über die Hemmungsmechanismen für die Reflexthätigkeit," etc., Berlin, 1863) which immediately drew general attention to the subject. It had been observed already that the reaction-time of a frog is greater before than after decapitation, or, in other words, that reflex actions are more quickly performed in the absence of the brain. Setschenow states, at the beginning of his monograph, that there were at that time two possible explanations of this increase of reflex-excitability consequent upon decapitation, viz.: *first*, that since the spread of sensory (afferent) impulses must tend to weaken them according to the area over which they are extended, those which cover the smaller area should give rise to stronger reflexes. Hence, when the head is cut off, because the sensory impulses are more confined the reflex of any given impulse is more intense. Or, *second*, that the brain normally exerts an inhibitory action upon the reflex excitability of the spinal cord. This latter theory Setschenow accepts and proceeds to verify, regarding it the more worthy of support since "Ed. Weber, speaking with a certain authority (on account of his celebrated discovery of the inhibitory influence of the vagus upon the heart), had first suggested that the will, whose seat is commonly supposed to be in the brain, is in a position to exert an inhibitory influence upon the reflex functions of the spinal cord" (*loc. cit.*, p. 1). This hypothesis seemed to presuppose the existence of "*inhibitory mechanisms*," and to find these Setschenow set to work. By cutting away the hemispheres no marked effect was produced; but whenever the optic lobes or optic thalami were removed, the excitability of the cord rose; whenever they were irritated it was depressed. Setschenow concludes as follows (*loc. cit.*, p. 35):

1. The inhibitory mechanisms for the reflex activity of the spinal cord have their seat, in the frog, in the optic lobes and corpora quadrigemina, and in the medulla oblongata.
2. These mechanisms must be regarded as nerve-centres in the broadest sense.
3. The afferent nerve-fibres form one (and probably the only) way for the excitation of these inhibitory mechanisms.

In the twenty-five years which have gone by since Setschenow propounded his theory of the existence of special centres for reflex inhibition, it has found numerous adherents and opponents. The former have added little enough to the evidence upon which Setschenow's theory

is based, while the latter have made it clear that the hypothesis is probably gratuitous, the facts involved being more easily explained otherwise. To give the whole history of this debate would carry us too far into details, and for these we must refer again to Eckhard (*Beiträge zur Anat. und Physiol.*, ix.). The tendency of physiologists to-day is to look upon the inhibition of reflexes, not as a peculiar function of a special inhibitory centre or centres, but as one phase of inhibition in general, somewhat as follows: The central nervous system is a system of centres—automatic as well as reflex—closely bound together by nerve-fibres. The separate centres are to a great extent independent, but by no means entirely so, each being more or less influenced in its activity by others. Into this central system (brain and spinal cord) impulses, recognized or unrecognized by consciousness, are continually flowing from the eye, the ear, the heart, the viscera—in short, through every afferent nerve. Within the system itself impulses are started by the automatic centres and sent along its length as well as outward. Each centre, therefore, is always affected more or less by every other, and by afferent impulses arising in the peripheral sensory end-organs. To remove a quantity of these inward-bound impulses is to alter materially the conditions affecting the centres. But to remove the hemispheres of the frog is probably to remove only a very limited and (in the frog) uninfluential group of automatic centres. To take away the optic thalami, optic lobes, and medulla, however, is to remove the most important of all the incoming impulses, viz., those from the eyes, the ears, and the great pneumogastric, which of all the nerves probably modify most the more purely mechanical functions of the cord. It is not surprising, therefore, that after decapitation the cord, freed from the interference ordinarily produced by these impulses, should work, from a mechanical point of view, more perfectly, passing into an abnormally sensitive condition analogous to hyperæsthesia. Or, again, to remove the cerebral hemispheres and then stimulate the mid- and hind-brain with salt, after the manner of Setschenow, thus producing a depression of reflex activity, is plainly to intensify the impulses passing down into the cord, and to increase interference. That salt does not so readily do this when applied to the cut end of the cord after the brain has been all removed, is probably because in the former case the salt-produced impulses were added to the ordinary impulses going from the hind-brain, while now they are alone; previously they acted upon a cord already normally "depressed," while now they act upon a cord abnormally exalted. On the other hand, stimulation of one sciatic inhibits more or less perfectly the reflexes performed by the other; and yet section of one is said to depress the reflex powers of the other. The fact is, we are not yet in a position to dogmatize upon the subject of reflex inhibition, and the whole subject urgently demands further elucidation.

The Time Element in Reflex Actions.—Exner has estimated the time required for a stimulus applied to one eyelid to make the other blink. A sharp electric shock was applied, for example, to the eyelid of one eye, and the interval elapsing before the other eyelid blinked was noted, and found to be 0.0662 to 0.0578 second, being less for the stronger stimulus. If these figures be taken to represent the reaction-time, it is possible, by measuring the nerves traversed and knowing the latent period of muscular contraction, to estimate roughly the time spent in the reflex centre, which is given as 0.0555 to 0.0471 second. Without placing too much confidence upon these figures, which are probably wide of the mark owing to the numerous sources of error involved, we may still believe that much the larger portion of the time is spent in the reflex centre. Helmholtz, so long ago as 1854, came to the same conclusion, estimating the reflex-time as twelve to fourteen times greater than the rest of the reaction-time. These results form one basis of the now general belief, that the passage of the impulse through the centre is not a mere transit but an actual change, in which considerable time is consumed.

Rosenthal (*Monatsbericht d. Berlin. Acad.*, 1873, 104) asserts that the reaction-time depends on the strength of the stimulus; the stronger the stimulus the shorter the time; and that it is greater when cross-conduction is necessary than when the reflex occurs on the same side as that where the stimulus is applied. The condition of the cord is also highly influential—fatigue delaying the reflex- and increasing the reaction-time. Wundt has confirmed Rosenthal in the statement that cross-conduction is slow, but denies that the reaction-time is dependent upon the strength of the stimulus.

The Effects of Drugs, Temperature, etc., upon Reflex Actions.—The detailed treatment of the effects of different drugs upon reflexes belongs to pharmacology. It will suffice here to mention only strychnine, the effects of which are peculiar and have a direct and important bearing upon the theories of reflex action.

Magendie, even as early as 1809, found that certain vegetal matters, from which strychnine was afterward extracted by Pelletier and Caventou, produced peculiar cramps, the seat of which appeared to be the spinal cord. The same fact was more securely fixed, by the use of the alkaloid in a pure state, by Marshall Hall, in 1833, and the spinal cord has ever since been regarded as peculiarly affected by this poison, the remarkable effects of which have caused it to be widely studied.

Stannius (*Müller's Archiv*, 1837, 223) proved that when the strychnized blood does not reach the cord no spasms ensue. H. Meyer (*Zeitschrift für rat. Med.*, v., 257) found that direct application of the drug to the motor nerves is ineffective. Bernstein (*Moleschott's Untersuch.*, x., 280, 298) showed that it does not act indirectly by poisoning the blood, but directly upon the cord, by introducing it into the circulation of a frog from which the blood had been washed out by salt solution, and noticing that the spasms occurred as usual.

Meihuizen (*Pflüger's Archiv*, vii., 201) made the interesting observation that the motor nerve and the energy of the muscle in a nerve-muscle preparation is not affected. The evidence against heightened excitability in the sensory nerves is less conclusive, but points in the same direction. Apnœa prevents or does away with the spasms of strychnine-poisoning, but the explanation of the fact is not clear. Of chief interest, however, are considerations relating to the changes produced by strychnine in the cord itself; and here two theories have been proposed. The first supposes that the excitability of the cord is enormously increased, so that the smallest stimulus produces comparatively great results in the centres. The second looks upon the spasms as due to a diminished resistance in the cord, which allows the incoming impulses to roam unrestrained, as it were, up and down among the centres. At first sight the two views do not seem very unlike; but the former presupposes a change in the protoplasm of the centres themselves, making them more "explosive" and thus overcoming the normal barriers in the cord; the latter regards these barriers as broken down by the strychnine, thus allowing the normal operations of the centre to work results unusually extensive.

Concerning the effects of temperature as a stimulus, enough has already been said above, but as to the influence of temperature upon the condition of the reflex apparatus it may be remarked, in general, that there is a certain temperature at which the reflex mechanism is most active, and above and below which reactions occur less readily. It depends, therefore, upon circumstances whether a rise or fall of temperature shall give better or worse results (*cf.* Eckard, *Beiträge*, etc., p. 135, and Sedgwick, "On Variations of Reflex-excitability in the Frog, induced by Changes of Temperature," *Studies from Biol. Lab. Johns Hopkins Univ.*, ii., 385).

Laws of the Propagation of Reflexes.—One of the earliest observations of "sympathy" and reflex action was, that it is not a matter of chance or indifference what action follows a particular stimulus applied to a particular spot. The most commonplace observation shows that weak stimulation of a special spot produces a certain result in certain muscles or glands, while a more powerful stimulus affects a more extensive set of muscles, etc. The earlier observers—Volkmann, Grainger,

Valentin, and others—contented themselves with stating that movements stand in a pretty definite relation to the spot of skin stimulated. But with strong stimuli, and especially with stimulation of nerve-trunks, other phenomena occur which cannot be so simply formulated. Thus salivary secretion and movements of the pupil may follow stimulation of the sciatic, of purely sensory cutaneous nerves, or even of membranes like the dura mater.

Accordingly, Pflüger ("Die sensor. Functionen des Rückenmarks d. Wirbelth., nebst einer neuen Lehre über die Leitungsgesetze der Reflexionen," Berlin, 1853) has laid down for the human subject a series of laws calculated to define the paths of propagation of reflexes, and called by him *General Laws of Reflex Actions.*

1. *Law of the Propagation of Unilateral Reflexes.*—Whenever muscular movements follow upon the application of a stimulus to a peripheral sensory nerve of one side of the body only, and occur upon only one side, they are invariably found upon the same side as the stimulus.

2. *Law of the Bilateral Symmetry of Reflexes.*—Whenever a stimulus has affected a reflex-centre so that movements occur not only upon the same, but also on the opposite, side, it invariably happens that only those motor nerves of the opposite side are affected which correspond to the motor nerves already affected upon the same side as the stimulus, *i.e.*, the muscular movements produced are bilaterally symmetrical.

3. *Law of the Unequal Strength of Bilateral Reflexes.*—Whenever the irritation of a sensory nerve produces bilateral reflexes of unequal strength, the stronger is always upon the side to which the stimulus is applied.

4. *Law of Irradiation.*—Whenever an afferent cranial nerve evokes reflexes, the impulses travel among the centres from before backward; but whenever an afferent spinal nerve has produced reflexes through its centre in the cord, the impulses spread from behind forward.

Other laws have been given, both by Pflüger and others, but all, including some of the foregoing, have been called in question by different observers, especially by Luchsinger (*Pflüger's Archiv*, xxii., 178, etc.). The whole subject needs further investigation.

Reflex Centres.—Besides the great automatic nerve-centres, such as those of the cortex, the cerebral hemispheres, the respiratory centre, the vaso-motor centres, the cardio-inhibitory, etc., we must suppose that the brain, and especially the spinal cord, is the seat of numerous, more purely reflex, centres. But when we are asked to prepare a map showing precisely where these different centres lie, it is evident that in only a few cases can positive statements be made. The method of searching for such centres consists in tracing the afferent and efferent nerves (when this is possible), and removing portions of the cord (or brain) successively until the ordinary function is stopped or interfered with. The difficulties met with in special cases may be illustrated by referring to the search for the centre (or centres) of reflex contraction of the pupil. Flourens was the first to locate a region in the brain the destruction of which would do away with contraction of the pupil, and he placed the "centre" for this function in the corpora bigemina and quadrigemina. Longet confirmed this statement and asserted that the hemispheres, cerebellum, corpora striata, and optic thalami, could be removed without interfering with reflex contraction of the pupil. Budge located the centre on the inner side of the two anterior of the corpora quadrigemina; but Vincent (1877) asserts that it lies at the upper end of the spinal cord.

It would lead us into too many details to follow up the history of the discovery of the numerous reflex centres now known or supposed to exist. Suffice it to say, that while many are assumed, few are very definitely located. The question, which is as old as the subject itself, whether consciousness extends into these centres or into the spinal cord at all, has been much debated, and is still unsettled. There is a certain amount of evidence which seems to some to make it likely, but to others is inconclusive. If a decapitated frog be hung up and have a bit of filter paper, soaked in acid, laid upon the skin near the anus, one leg will generally be lifted and a brushing or sweeping movement will be made, as if with a *purpose* to wipe the paper off. Still more purposeful appears the movement which is made, oftentimes, if the leg ordinarily used to make the movement be gently held and prevented from moving; in which case the other leg (commonly not used for the movement) is called into requisition and makes wiping movements. This certainly seems to indicate intelligence, though intelligence of this sort is not necessarily accompanied by consciousness. It seems possible, in cases like this, to suppose merely a complicated and very perfect reflex action going on without the existence of consciousness. Moreover, the experiments of Fratscher (see p. 155), in which normal frogs sat motionless in water gradually heated from the normal to a fatal temperature, lead us to rate the normal consciousness of the intact frog as certainly not very high, at the best.

In conclusion, it must not be overlooked that the practical importance of reflexes is very great, not only to the individual, most of whose "experience" is hardly more than the resultants of repeated reflexes, but also to the practitioner of medicine, both as regards diagnosis and treatment. The digestive and other disorders due to teething in infants, the headaches resulting from decayed teeth or from defective vision, the vomiting in pregnancy, the coughing from chronic laryngeal irritation, and the like, are well understood. Less clear are the effects of over-exertion, the reactions from the stimuli—infinite in number and variety—of city life, of changes in environment, climate, food, and dress; but that these are real and produce their own peculiar reflexes cannot for a moment be doubted. The science of hygiene—if not the science of medicine—must, undoubtedly, in the future give greater heed to these multifarious stimuli, for the sake of their effects.

Therapeutics—consciously or unconsciously—has long made use of reflex actions. The use of the blister, the sinapism, and the hot iron reaches back to a very early time. Applications of heat and cold are often indispensable; and rest, *i.e.*, freedom from the usual stimuli; and sport, *i.e.*, the application of agreeable stimuli—are universally and justly recognized as the chief instruments of recreation and refreshment. Yet it is not so well recognized as it ought to be that the skin, and hence the whole nervous system, may be as truly "scourged" by sudden changes of temperature in a "trying" climate, or by clothing, as by the blister or the hot iron; and that the sensitive retina or inner ear, may be "scourged" as certainly as the skin with which it is homologous. The practical value of reflexes lies principally in the fact that in their use or disuse we have a means of reaching or resting the central nervous system, and hence of influencing more or less nearly every action or condition of the whole organism. *W. T. Sedgwick.*

REGISTRATION OF DISEASES. That knowledge which tends most directly to preserve life is the knowledge of the most common causes and conditions which lead to death. As, according to Herbert Spencer, that knowledge which tends directly to preserve life is "of most worth," so, to the human race in general, the most important questions to be settled are the causes and conditions which lead to most deaths. That the registration of deaths and their causes would be attempted by many governments was therefore to be expected.

At first sight, however, it seems strange that in this most important work so little progress has been made. One of the principal reasons seems to be, that for success in gathering such statistics there is needed the co-operation, not only of many individuals, but of many classes of people; and the importance of the subject has not been so clearly impressed upon the average person as to secure that co-operation. In this country it has been almost impossible to obtain reliable statistics of deaths or their causes, except in limited areas, such as in cities where burial permits are required for the purpose of securing such statistics. And when reliable statistics of the causes of deaths are secured, the compilation of such statistics, in ways to teach valuable general truths, is ex-

tremely difficult. Expert ability of a high order is required, and much experience in such work. The common way, however, is to entrust this work to a new man each time. In some of the States the compilation of the vital statistics is entrusted to an ordinary clerk in the State Department. Even the general government at Washington has as yet no permanent office or officer for census work, but nearly every United States Census is managed by new men, who are obliged to learn anew this most difficult of all scientific work. There is hope in the fact that people are coming to appreciate the value of statistics relating to labor, and bureaux of statistics are being demanded and created, which in time will undoubtedly do something to teach all classes of people the value of statistics, the importance of continuous systematic work for their collection, and the necessity for their compilation by skilled and experienced men.

Much has been learned from the registration of deaths; it has shown us the relative importance of the various diseases, the relative danger from each to persons of the two sexes at the different ages, and many other useful facts. When, however, we come to study the real causes of deaths, we find that we need to know a great many facts which no ordinary statistics of deaths supply. We need statistics of the meteorological and other conditions antecedent to, and coincident with, the deaths; and since, in most cases, the fatal sickness (the name of which only is given as the "cause of death") was incurred some time previous to death, the date of the death is not sufficient—we need to know the average duration of each of the diseases, in order to know how far back in time to look for the real cause of the disease. It may be thought that, as regards many of the ordinary diseases, we already know the causes, and that concerning those diseases there is no need for further research. Thus small-pox, scarlet fever, consumption, and some other diseases are known to be caused by special contagia, which are conveyed from the sick to those who become sick. But it has recently been shown by statistics[1] that the rise and fall of these diseases are apparently controlled by meteorological conditions; so it appears that, under some meteorological conditions, either there is very much less susceptibility to the disease, or the contagia are much more readily destroyed, or both; and it becomes important to gain further information which may teach us how to favor the destruction of the contagia, or to promote the insusceptibility of the people.

Registration of Sickness.—For gaining a knowledge of the causes of diseases, the registration of sickness is on some accounts more important than the registration of deaths; and in various ways efforts have been made to secure records of sickness; medical college professors have recommended to students that they record their cases; medical societies have appointed committees on prevalent diseases; the British Medical Association has inaugurated the "Collective Investigation of Disease," and in many ways the profession has shown its high appreciation of such records for the advancement of the medical sciences.

In recent times, extensive registration of disease has occurred in some of the great hospitals, in the marine hospital services, in the navies, and especially in the great armies of the world; and, in this country, the medical and surgical histories and records of the War of the Rebellion are a vast mine of valuable data, which may be made to yield knowledge of the causes and conditions of sickness from many of the most important diseases, which should go far toward teaching mankind how to avoid and prevent them. But there are difficulties in the way of inducing people to utilize these valuable records, which it may take many years to overcome. As it is not profitable for any class of persons, unless it be the insurance companies, to engage in such work, the people—that is to say national or state governments—must provide the means. The publication of the mere statistical tables is only supplying the raw material, for the utilizing of which expert ability is required, and graphic illustrations of results are essential to its proper and forcible expression; and then, on the part of those generally who are to receive it, knowledge of statistical methods, of the theory of probabilities, and how to use graphic representations, is required for its correct appreciation.

It would seem that a government can have no better function and no higher duty than the supplying of such information and knowledge, for saving the life and preserving the health of the people for whom the government exists.

The army and navy records have one advantage over other registrations of disease—namely, that of a statement of the population in which the sickness occurred—the "mean strength" of the army supplying this factor for that service. On the other hand, the registrations by civil governments give us the sickness among both sexes, at all ages, and under all ordinary conditions of living.

Outside of army and navy records, the earliest systematic effort to secure a continuous record of sickness by many observers, was that of Benjamin Ward Richardson, of London, England. Dr. Richardson says that the idea of making a registration of disease originated with him in 1852, and in 1854 he began to carry it out in his new journal of public health—the *Sanitary Review*—then a novelty in the literature of Great Britain. His registration tables were published quarterly for four years, at the end of which time observations were being taken from sixty stations, extending from St. Mary's, Scilly, in the extreme south, to Lerwick, almost in the extreme north of those islands.

Unable to continue the inquiry in consequence of the increasing expense, which multiplied with the success of the experiment, he tried, through Sir Benjamin Hall, then President of the Board of Health, to transfer the labor to the government without asking anything for himself in the matter. The suggestion was kindly received, but declined.

Dr. Richardson read a paper on this subject to the Social Science Association, at its meeting in Dublin, the meeting being presided over by the late Lord Brougham. This paper is published in the transactions of the Association for 1861, pp. 535–546.

In this country the honor of pioneer effort to have such registration of sickness done by the government, apparently belongs to the State Board of Health of Massachusetts, which, on November 1, 1874, issued a circular to "a large and select number of physicians in full general practice, in various parts of the State."[2] The plan was for each physician to send each week to Dr. F. W. Draper, in Boston, "the registrar of this new Bureau of Health correspondence," a postal card "report of diseases prevalent during the week ending Saturday, . . . 1875." From these reports a weekly bulletin was published, showing, for each of seven districts in Massachusetts, the prevalent diseases and facts of interest relative to the rise and decline of contagious diseases. At the close of the year a summary of the results was published, containing two charts showing by weeks the rise and fall of fourteen important diseases. Being for only one year, and compiled by weeks, the curves in those charts are not steady, but the fluctuations would undoubtedly disappear, in accordance with well-known laws, with more numerous occasions and a greater number of reports. These curves are very instructive, indicating as they do the strong influence which the season of year has upon sickness from each of these fourteen important diseases. In his report Dr. Draper says: "The sensitiveness of the public health to weather variations has been shown repeatedly by means of the weekly returns. A sudden change in temperature or in humidity has again and again indicated its effect upon the amount and gravity of the prevailing diseases. A single instance, which many persons in Massachusetts will recall, may be cited as an example of this. The fourth week in April, the week in which the centennial celebrations at Concord and Lexington occurred, was marked by a severe cold snap after an interval of mild weather. The sickness returns for the week represented a very decided increase of acute diseases; bronchitis, influenza, rheumatism, pneumonia, whooping-cough, measles, scarlatina, and sore throat were returned as being much more prevalent.

"It is one of the advantages of such a system of sickness-registration that it shows at any time, and without delay, the effect of the weather changes, making a far more prompt and satisfactory exhibition of the influence of such changes upon the public health than is possible with the mortality table which gathers the more distant, indirect, and partial results of the same phenomena."[3] No attempt was made, however, to bring together with these data similar exact data relative to meteorological conditions, and by this comparison to learn the causes or conditions of the rise and fall of the several diseases.

It is much to be regretted that after a single year's trial with reports of sickness, this work was discontinued by the Massachusetts Board of Health.

On July 11, 1876, the Michigan State Board of Health inaugurated a system of weekly reports of sickness by prominent physicians in active general practice in different parts of the State.[4] At first it followed somewhat closely the form and methods employed in Massachusetts, but as time and experience suggested changes, the methods and forms have been amended. One of the first and difficult changes made was from the term "prevalent" applied to disease, because there could be no scientific exactness so long as it was employed. Now, each observer reports the cases of each disease *under his own observation* in his locality; or, if he does not like to report the number of cases, he may state the "order of prevalence" of each disease, but it is confined to cases under his own observation.

Not Necessary that all Sickness shall be Recorded.—Many persons at first find difficulty in understanding how it is possible to use statistics unless the statistics include all of the phenomena to which they relate, and most physicians at first lean toward an effort to learn and report all of the sickness in their locality. To do this is entirely impracticable, and will probably remain so for generations to come; and it is not necessary, because statisticians now know how to use statistics which do not include all the cases. The theory of probabilities, the law of averages, and the disappearance of minor errors through the multiplication of instances and observations, supply the principal foundations for the work of statistics. But this is not the place to more than refer to that part of the work.

Essentials for the Registration of Sickness.—The essentials for a good registration of the sickness from the most common diseases (the most important diseases to be studied, because they cause the most sickness) are, 1, a sufficient number of reliable physicians in active general practice; 2, the distribution of these observers so as fairly to represent the area to be studied; 3, accurate reports showing for each disease its presence or absence (under the reporter's own observation), and preferably the number of cases; 4, reports, or at least records, of these facts to be made so soon after their occurrence that none of them shall be forgotten; 5, the compilation of these reports by an expert statistician who must be honest, and should also be a physician well grounded in the physical and biological sciences; 6, the union of the data thus obtained with similar data of meteorological conditions recorded by competent meteorological observers, using standard instruments, self-registering so far as practicable, and the records to be made tri-daily.

Not Essential that the Population be Known.—One hinderance to progress in the registration of diseases is the idea that no use can be made of records of sickness without a knowledge of the population in which the sickness occurs. If the number of inhabitants is not known, it is not possible to learn the proportion sick from any given disease; but that is not the most important knowledge to be gained in searching for the causes of diseases; and it is quite possible to compare one week, or other specified time, with another with reference to the sickness from a given disease, without any exact statement of the number of inhabitants. It has been found that in Michigan the distribution of sickness *locally* follows about the same law that it does *generally* throughout the State—that is to say, the "order of prevalence" of a given disease in localities "where present," is found to be practically about the same as the "per cent. of all reports received which stated the presence of the disease." It follows that, in order to learn the rise and fall of the disease over a considerable area, it is not even necessary to know the number of cases of each disease, but only to know the fact whether each observer did or did not, during the given short time, observe a case of the given disease; then a comparison of the per cent. of reports, stating the presence of the disease in the several weeks or months, will show the comparative area of prevalence of the disease in each specified period of time. It is advisable, however, that the number of cases be reported, because this gives opportunity for the study of the subject locally; and this leads to the remark that, after the *meteorological* conditions coincident with the rise and fall of each disease shall have been learned for all localities, there will remain other conditions which must be studied in order to learn why the sickness is not always associated with the same meteorological conditions in every part of the world.

Graphic Comparisons are Essential.—No ordinary person can, with reasonable effort, so master an ordinary table of mortality or sickness from a single disease by months in a single year, as to secure a correct and complete mental picture of the relations of the several months each to every other month in the year, and at the same time compare the same with a similar table relating to a condition such as temperature, which may be supposed to have relation to the sickness or mortality. If any person doubts this statement let him try it, as the writer has many times done, and afterward compare his effort with a good diagram accurately drawn to scale. As the carpenter needs his square to measure his work, and his try-square to test the angles, so it is true, and should be generally understood, that some sort of graphic representation is essential for any degree of accuracy in a statistical comparison.

Even in this discussion, diagrammatic representation is almost essential to a clear understanding of the subject.

Inasmuch as there can be no progress in utilizing the results of the registration of disease without a proper use of diagrams, every one interested in the medical sciences should be able to read easily those which are correctly constructed, and to reject those which are not correct.

The Essentials for Graphic Comparison.—The making of diagrams is very easy when one knows how; but when two or more curves are to be compared with reference to a law of causation, there are a few essential conditions which do not seem to be generally known, and which are seldom complied with by those who publish such diagrams. One of the most important principles to be observed is to insure that the fluctuations, in two or more curves to be compared, shall be measured by the same measuring rule. No one would think of comparing one piece of timber measured in feet with another measured in yards without first converting one measurement into its equivalent in the other; yet, substantially, this error is quite frequently found in published diagrams. One difficulty seems to be to firmly grasp the idea of what is to be measured and compared, and another, the idea of how to compare such dissimilar statements as degrees of temperature with per cent. of sickness.

In each such curve representing dissimilars the *variation* is to be measured and compared, and whether stated in inches or pounds, by number or by per cent., these variations may easily be brought to a "common denominator," so to speak, by planning the diagram so that the greatest variation, or extreme range, in each curve shall be the same as it is for every other curve with which it is to be compared. This is simply done by making the range of the diagram the range for each curve—the highest and lowest parts of each curve reaching the highest and lowest parts of the diagram.

This insures that the extreme range shall be the same for each of the curves. If then the variations in one curve are quantitatively related to the variations in another curve, the two curves will sustain the same relations to each other throughout their extent; otherwise they will not do so, and their lack of parallelism will be apparent.

TABLE 1.—*Exhibiting by Months, for a Period of Eight Years,* 1877–1884, *the Relation of Sickness in Michigan from Pneumonia, to the Average Atmospheric Temperature.*

	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
Av. Temperature. Degrees Fahr.	21.43	25.60	31.04	44.48	56.60	65.54	70.68	68.85	62.05	51.34	35.99	27.25
Av. Per Cent. of Reports stating Presence of Pneumonia	62	66	62	56	42	27	18	14	18	23	35	48

To find the scale of value of numbers applicable to a curve representing a line in a table, subtract the lowest from the highest statement to be represented; this will give the extreme range (which equals the entire distance of the diagram), and that sum may be divided into such parts that the numbers may be conveniently stated, and the entire distance occupied may be divided into parts proportionally. For instance, for a full-page (octavo) diagram, leaving room for the head and foot-notes, 6.375 inches may be occupied by the curves (see Fig. 3229).* Suppose the highest number to be represented (stating per cent., degrees, or cases) is 66, as it is in the lower line in Table 1, and the lowest number 14, the difference (52) is to be distributed over the 6.375 inches, one (per cent. or case, etc.) then equals 0.122 inch, ten equals 1.22 inch. The nearest convenient number above 14 is 20, and lines so placed that they will be opposite the value of 20, 30, 40, 50, and 60 may conveniently be used, because they are even numbers which can be easily divided. There being the value of 10 (cases, etc.) between them, these lines will be 1.22 inch apart.*

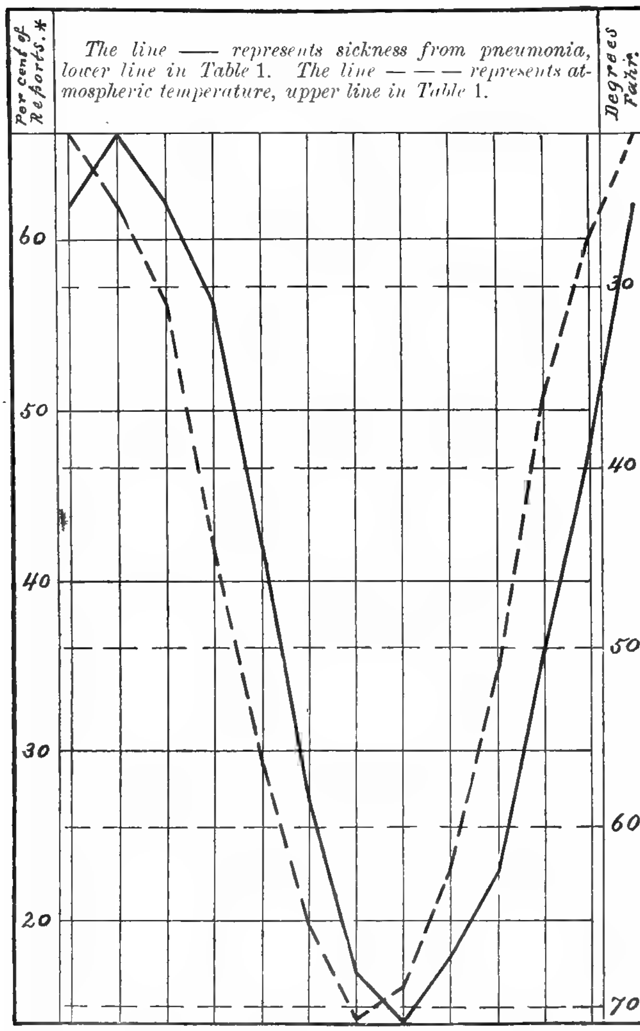

FIG. 3229.

To make a scale to use in dividing such a distance as 1.22 inch into ten equal parts,† draw along a slip of stiff paper two lines 1.22 inch apart, then place across one end of these lines a rule having ten divisions, covering a space a little more than the space between the two lines; move the rule until it crosses the space diagonally, in such a way that the nine lines on the rule will divide the space equally, and make a diagonal row of dots opposite the nine lines; move the rule along the slip a few inches and repeat the dots; then rule a short line on the end of the paper slip exactly in line with each two corresponding dots; the spaces between these lines will then all be 0.122 inch, and in this assumed case (Fig. 3230) will be the space which will represent one.‡ The ruled end of the slip of paper is then a scale which will enable a person to measure exactly the space to be allotted to any number from one to ten. But this measuring-scale is only applicable to curves representing what may be measured by the same scale and stated in precisely the same manner. It may, for instance, apply to many curves representing sickness, to many representing deaths, to many representing temperature, or even to one curve representing sickness and one representing deaths, provided both are stated by numbers of cases; but it cannot apply both to sickness and to temperature, because the values must be differently stated, and it is not usual that both values are such as to be conveniently stated together; therefore it is usually necessary to make such a scale and a set of marginal figures for each dissimilar curve in a diagram. For instance, in the diagram shown in Fig. 3229, the entire range of temperature, which, according to my rule, must equal the entire range of the diagram, amounts to 49.25 degrees, and is between 21.43° and 70.68°. In order that the variations in the temperature may be compared with the variations in the sickness, this 49.25 degrees must be proportionately distributed over the same space as that occupied by the curve of sickness. This is done, in the manner described for the sickness curve, by dividing the 6.375 inches by 49.25, when it is found that ten degrees of temperature should occupy 1.29 inch.‡

This 1.29 is subdivided by means of a rule placed diagonally, as previously described, and marginal figures are placed opposite values convenient for use—such as 30°, 40°, 50°, 60°, and 70°. When this is done

* The engraver has reduced the size of this diagram, so that instead of the curves occupying 6.375 inches vertically they occupy only 4.675 inches; but the principle of subdividing this space remains the same as described.

* The illustrative diagram (Fig. 3229) having been reduced in size, these horizontal lines are shown only .90 inch apart, instead of 1.22.

† These directions for making a scale to use in constructing or reading such a line as is the continuous one in Fig. 3229 (representing per cent. of reports showing sickness from pneumonia) were written before that diagram was reduced, and are retained because they apply to a size believed to be especially useful. For the continuous line in this diagram as reduced and here printed, the subdivision should be of .90 inch instead of 1.22, and the scale would be like that given on page 163—each subdivision representing one per cent. of reports.

‡ This was written with reference to the diagram (shown in Fig. 3229) as drawn, not as reduced in size by the engraver.

and the curves have been made, both curves have what, for lack of a better term, may be called a "common denominator," that common denominator being the total variation during the entire period of time. The curves have this in common—that the entire range of each occupies precisely the same space as does that of the other, and each curve as a whole, has the same space-value.

Referring to Fig. 3229, if the entire range (fifty-two per cent. of reports) of sickness from pneumonia is

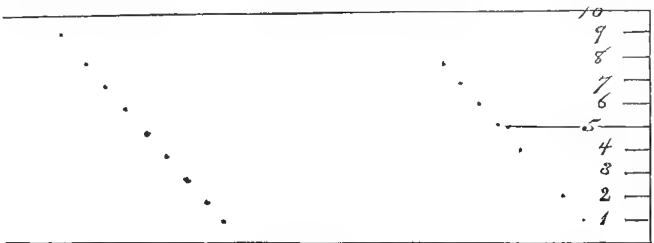

FIG. 3230.

caused by, or is quantitatively related to, the entire range (49.25°) of atmospheric temperature, then it seems reasonable to suppose that the sickness from that disease may be directly proportional to the temperature in every month of the year, in which case the curves for sickness and for temperature would be parallel throughout. The amount of parallelism in this particular case may be seen in the diagram.

It is well to have the perpendicular lines (ordinates), not the spaces between them, represent the months or other specified periods of time, then the exact crossing of the line (ordinate) by the curve is easily seen, and the degree or value of the intersection may be learned by referring to the figures in the margin; and each curve, the values for which have to be differently stated, requires its own scale and set of marginal figures, which for comparison may all be on one side of the diagram, but for distinctness and ease of reading may well be separated (as in the diagram above referred to).

When it is practicable, it seems most logical to have the degree or value of the meteorological or other condition increase from below upward, so that, as the curve representing a disease rises or falls, the fact whether the condition rises or falls will be apparent; but another fact seems to be of even greater importance to be learned, which is, just how closely, quantitatively, the two curves are related to each other, and this cannot be accurately estimated when the curves run in opposite directions; therefore the curves should accompany each other, whether or not both marginal scales read in the same direction.

Results of Registration of Sickness.—The publication of the results of the registration of sickness in England, in 1854–58, has already been mentioned.

The work in Massachusetts showed that for a single year (1875), in that State, the sickness from diarrhœa, dysentery, cholera-morbus, and cholera-infantum was greatest in August and September; from typhoid fever, in September and October; from influenza, bronchitis, and pneumonia, in the cold months. The published results contain no tables, but the charts, accurately drawn to scale, are valuable, and will undoubtedly yield much useful material to anyone who will mine it.

Some of the results of the registration of sickness in Michigan since 1876, have been published in the several annual reports of the Michigan Board of Health. In the earlier reports little more is recorded than the data, but their elaboration is commenced in ways which may suggest uses to be made of the statistics. Curves representing the sickness from each of several important diseases illustrate the report each year, and similar curves, representing the principal meteorological conditions, permit of comparison therewith. The work has now been in progress long enough to make it possible to state just what relations exist (in Michigan at least) between each disease and each important meteorological condition; and in the later reports this part of the work is commenced,[5] not, however, by presenting all of those relations, but by selecting for presentation such as seem to have causal relations to diseases of most importance. Briefly, it may be stated that the evidence seems to show quantitative (and presumably direct or indirect causal) relations between temperature of the atmosphere and all important diseases of the lungs and air-passages, including pulmonary consumption, the number of cases of these diseases rising after the temperature falls and falling after the temperature rises.[6] The rise and fall of a few diseases known to be communicable are also apparently controlled by the atmospheric temperature.[1] Intermittent fever appears to be quantitatively related to the average daily *range* of atmospheric temperature.[8] The curve for remittent fever appears to follow more or less closely the reversed curve for atmospheric ozone. The relations of atmospheric temperature to sickness from diarrhœa, dysentery, cholera infantum, and cholera morbus are graphically shown.

Such knowledge as that intestinal diseases prevail in hot weather, and that diseases of the air-passages prevail in cold weather, has been possessed by the medical profession since the time of Hippocrates, but it has had no accurately recorded, scientific basis, and no great progress can be made in eliminating the accidental, and in isolating the causal relations until records of each important meteorological and other condition shall have been passed in review, interrogated, and cross-questioned.

It would seem that a beginning has now been made in the scientific registration of diseases, by the method known as the "Collective Investigation of Disease," which, started by the British Medical Association, is spreading through this and other countries; by such governmental works as are recorded in the "Medical and Surgical History of the War of the Rebellion" in this country; by the systematic registration of vital statistics by State and other governments, and the periodical collection of such statistics by means of censuses; and finally, by the systematic and continuous registration of sickness, such as was started in England under the leadership of Dr. Benjamin Ward Richardson, was taken up for a time by the Massachusetts Board of Health and by the Provincial Board of Health of Ontario, and has been, since 1876, continuously maintained by the Michigan State Board of Health. *Henry B. Baker.*

REICHENHALL, in Bavaria, distant four hours by rail from Munich, is a popular watering-place, visited chiefly by those suffering from obstinate catarrhal affections of the respiratory organs. The waters are also recommended in the treatment of rickets, gout, anæmia, and scrofulous adenopathies. There are about twenty saline springs at Reichenhall, the most important of which are the Edelquelle and the Carl-Theodorquelle. The waters, mixed with a strong brine, are used chiefly for bathing, though they are also drank in small quantities. The climate is mild and agreeable. The season extends from the first of May to the end of October, the last month being for those who wish to take the "grape-cure."

T. L. S.

REINERZ is a pleasantly situated Prussian health-resort. It lies at an elevation of about 1,800 feet above the sea. The air is pure and fresh, free from sudden changes

of temperature, but not very mild. The following is the analysis of the three springs used for drinking purposes, as given by Kisch in Eulenburg's "Real-Encyclopädie." One litre contains of :

	Kaltequelle.	Lauequelle.	Ulrikenquelle.
Bicarbonate of iron	0.017	0.051	0.051
Bicarbonate of manganese	0.001	0.004	0.001
Bicarbonate of sodium	0.319	0.786	0.622
Bicarbonate of calcium	0.655	1.180	1.024
Bicarbonate of magnesium	0.206	0.356	0.332
Chloride of sodium	0.006	0.015	....
Chloride of potassium	0.011	....	0.008
Sulphate of sodium	0.022	....	....
Sulphate of potassium	0.127	0.084	0.958
Silicic acid	0.036	0.065	0.016
Total	1.400	2.541	3.012

There is a large proportion of free carbonic acid gas.

There are several other springs, the waters of which are used for bathing. Besides these, therapeutic use is made largely of milk and whey from cows, goats, sheep, and asses.

Reinerz is visited chiefly by sufferers from laryngeal and bronchial catarrh, pulmonary phthisis, and chronic catarrhal diseases of the digestive organs. It is also much frequented by those run down by overwork or from other causes. The season extends from May to October. *T. L. S.*

REMEDIES, ANTAGONISM OF. Under this head will be considered only the physiological antagonism between certain drugs. Physiological antagonism between two drugs may be so extensive as to practically include almost their entire range of action, or it may be limited to one or more of their actions. We have many examples of the latter, but few indeed of the former. In fact, it is difficult to mention any two drugs the antagonism between which is complete.

Very numerous experiments have been performed on the lower animals with the view of establishing the principles which underlie the antagonistic effects between certain drugs, and also with the view of endeavoring to extend our practical knowledge in the treatment of cases of poisoning, especially of alkaloidal poisoning. Unfortunately, the results are not at all commensurate with the time and labor spent in the study of this subject. The results, however, are extremely interesting in a pharmacological sense, and have done much to extend our knowledge of therapeutics in general.

It would serve no useful purpose, even if space admitted of it, to give in detail the numerous drugs whose antagonistic effects to those of others have been carefully worked out. After all, the practical outcome of our knowledge of this subject is not so much that we can make use of it in the treatment of cases of poisoning, but rather that it saves us from prescribing drugs together that have marked antagonistic effects. It is exceedingly common to find in the one prescription drugs having directly antagonistic effects. We might instance the following, which have come directly under our own observation : The administration of digitalis and aconite in a case of loss of compensation in mitral insufficiency ; the combining together of bromide of potassium, calabar bean, and strychnine in a case diagnosed as subacute transverse spinal myelitis. No doubt, these prescriptions were put together on the "gunshot" principle. Still, if the writers had had clear and distinct views of the physiological antagonism existing between the different agents in their prescriptions, they would never have been written.

The physiological antagonism between the following drugs only will be considered :

1. Chloral and strychnine.
2. Digitalis and aconite.
3. Muscarine and atropine.
4. Atropine and pilocarpine.
5. Atropine and morphine.

1. *Chloral and Strychnine.* Both of these agents act principally on the respiratory centre and the spinal cord.

Chloral is a powerful respiratory depressor, while strychnine, on the other hand, has a powerful stimulating effect on the respiratory centre. It has been conclusively proved that after the administration of a fatal dose of chloral to one of the lower animals, life may be saved by injecting strychnine ; but I have been unable to find a single case of chloral-poisoning, in man, where there is clear evidence that life has been saved by strychnine. Numerous cases are recorded where it has been used, but in conjunction with other agents. As chloral causes death by depressing the respiratory centre, it certainly is reasonable to expect that this effect will be antagonized by an agent which has a powerfully stimulating effect on the same centre.

Chloral is, however, more of an antagonist to the effects of strychnine, than strychnine is to those of chloral. A large dose of chloral may kill before the action of strychnine is manifest. Strychnine kills by producing asphyxia, from spasmodic arrest of the respiratory muscles. It brings about greatly increased excitability of the motor centres in the spinal cord. The respiratory muscles share in the spasms with the other muscles, and death is due to the fact that they are contracted in inspiration. There are a few cases on record in which the lethal effects of strychnine in man have certainly been antagonized by chloral. In treating a case of strychnine-poisoning by chloral, the latter should be pushed until the spasms are allayed; the amount required to effect this purpose varies greatly.

Judging from the often beneficial action of choral in tetanus, we would expect a similar effect from chloral in strychnine-poisoning, which is practically an artificial tetanus. On the motor centres of the spinal cord the antagonism between chloral and strychnine is very complete, chloral being one of the most powerful motor depressants, while strychnine is the most powerful motor stimulant, that we have. Chloral being a more powerful motor depressant than strychnine is a respiratory stimulant, it naturally follows that chloral is more effective as a physiological antidote to strychnine than the latter is to chloral.

2. *Digitalis and Aconite.* There is a striking difference between the action of digitalis and that of aconite on the heart. This difference is more marked on the hearts of cold-blooded animals than on the hearts of warm-blooded animals. On applying a small quantity of aconite to the exposed heart of the frog it rapidly comes to a standstill in dilatation ; if now we apply digitalis, the distended ventricle soon recovers itself and returns to its normal condition. If more digitalis be injected, the systole becomes longer and longer and the diastole less complete, especially at the apex, which remains white and firmly contracted. This gradually extends over the whole ventricle, the heart finally coming to a standstill in firm contraction.

When either digitalis or aconite is given in such doses as to produce standstill of the heart, the pulse becomes quick, and the blood-pressure falls. "In aconite-poisoning the aortic pressure falls because the over-distended ventricle is unable to contract on its contents. Each contraction only sends a small quantity of blood from the upper portion of the ventricle. In digitalis poisoning the aortic pressure falls, because the over-contracted ventricle permits but little blood to get into it, and can, consequently, send but little forward. The result is similar in both cases, but the cause in one case is just the reverse of that in the other" (Balfour).

Owing to the slowness of the action of digitalis on the heart, even when administered hypodermically, it is doubtful whether it is able to antagonize the effects of a large dose of aconite. So far, I have been unable to find in the literature any case of aconite-poisoning treated simply by digitalis. In fact, from our present knowledge it would be very unsafe to trust to digitalis alone in such cases. The antagonism existing between these two agents is more interesting from a pharmacological than from a toxicological point of view.

3. *Muscarine and Atropine.* Muscarine, an alkaloid obtained from the fly agaric (Agaricus muscarius), has marked antagonistic effects on all the peripheral organs paralyzed by atropine. The antagonism existing between

these two agents is probably the most extensive known. Muscarine is a powerful cardiac depressant. It causes salivation, lachrymation, as well as an increase in other glandular secretions, violent contractions of the gastric and intestinal muscles, with consequent vomiting and diarrhœa, contraction of the bladder, spleen, and uterus. It produces contraction of the pupil, and spasm of the accommodation. All these effects of muscarine rapidly disappear under the influence of atropine, and, further, they do not appear at all in an animal that is completely atropinized.

Muscarine causes death by cardiac paralysis. The fatal issue can be averted by the use of atropine.

4. *Atropine and Pilocarpine.* The antagonism existing between atropine and pilocarpine is very extensive, including almost the entire actions of these two agents. Pilocarpine causes an increase in all the secretions, especially of the secretion of the sweat and saliva. The salivation is due to irritation to the terminal filaments of the chorda tympani in the glands. It is rapidly arrested by atropine, and it can be prevented entirely by giving atropine previously.

The perspiration which is due to stimulation of the sudoriparous nerves and the sweat centres can also be prevented and arrested by the use of atropine. The other secretions are stimulated by pilocarpine, and arrested by atropine.

Pilocarpine contracts the pupil and gives rise to spasm of accommodation. Atropine dilates the pupil and causes paralysis of accommodation.

Pilocarpine slows and weakens the pulse, and lowers the blood-pressure. Atropine quickens and strengthens the pulse, and raises the blood-pressure. Atropine stimulates the respiratory centre. Pilocarpine has no definite effect on it.

Cases are recorded where pilocarpine has been used successfully in cases of poisoning by atropine, but it is doubtful whether the success was really dependent or not on the treatment. The power that pilocarpine has in antagonizing the effects of atropine is much less than the power of atropine over pilocarpine. When, further, we remember that in many cases of atropine-poisoning death results from a paralysis of the respiratory centre succeeding the over-stimulation first induced, it is not to be expected that much good will result from pilocarpine.

5. *Atropine and Morphine.* The antagonistic action between atropine and morphine is, in a practical point of view, the most important that we have to deal with. Cases of poisoning by opium and its alkaloid are very numerous, and owing to the alleged powerful antagonistic effects between it and atropine, numerous cases are on record in which this alleged power has been tested.

Atropine and morphine are antagonistic in their action on the pupil, the former causing dilatation, the latter contraction. In cases of poisoning by opium we do not always find the pupils contracted.

Morphine diminishes or arrests the peristaltic movements of the intestines, while atropine has a contrary effect. The functions of the heart are not greatly influenced by morphine; atropine, however, causes a marked increase in the number of beats. The effects on the respiratory centre are antagonistic. This is *the* important antagonistic action of these two agents. Morphine causes death by paralyzing the respiratory movements, while atropine stimulates the respiratory centre. In over-doses, however, this stimulating action may be followed by a depressing one. There is a general consensus of opinion in the profession that atropine is very efficient as a physiological antidote to opium-poisoning. Numerous cases are recorded where, apparently, death from an over-dose of opium or its alkaloid has been averted by the administration of atropine. The literature of this subject is now a very extensive one. Leukartz (*Deut. Arch. für klin. Med.*, Band 40, p. 574) gives a very complete *résumé* of the cases of opium treated by atropine. In all he has collected fifty-nine cases of opium-poisoning where atropine was used. In by far the greater number of these cases other measures were employed also. Artificial respiration, strong coffee, emetics, ammonia, alcohol, etc., were the principal adjuvants to the atropine treatment. Seventeen of the fifty-nine cases died, being a mortality of 28.8 per cent.

Leukartz believes that the essential effect of the opium —the coma—is increased rather than made less by the action of atropine; and further, that atropine is powerless in combating the great danger in opium-poisoning—the paralysis of the respiratory muscles. He has collected 73 cases of opium-poisoning in which atropine was not used in the treatment, and there were only 11 deaths, a mortality of fifteen per cent. We thus have a mortality of 28.8 per cent. in the cases where atropine was employed, and a mortality of fifteen per cent. where it was not used. Leukartz from his researches comes to the following conclusions:

1. That the alleged physiological antagonism between morphine and atropine has not one single certain observation for its foundation.
2. That in the treatment of morphine-poisoning by atropine no certain improvement is to be expected.
3. That the treatment of morphine-poisoning should be carried out rationally (artificial respiration, etc.), and not by the exhibition of an alleged physiological antagonist.
4. That statistics show that the former method is much to be preferred to the latter.

Leukartz's conclusions may appear rather startling to the many who have an unbounded faith in the value of atropine in opium-poisoning. Upon a close examination of them, however, they appear to be well grounded, being founded on facts. *James Stewart.*

RENNES-LES-BAINS is a spa in the Département de l'Aude, France, lying on the Salz River, at an elevation of 1,045 feet above the sea. There are five springs, the waters of which are administered both internally and externally. The springs are known respectively as the Bain Fort, Bain Doux, Bain de la Reine, Source du Pont, and Source du Cercle. The water of the Salz River, which contains the chlorides of sodium and magnesium, and the sulphates of sodium, calcium, and magnesium, is also used for drinking mixed with the spring waters. The following is the analysis of two of the springs, according to Ossian Henry (Dechambre's "Dictionnaire Encyclopédique"). In 1,000 parts there are of:

	Bain Fort.	Bain Doux.
Calcium carbonate	0.250	0.140
Magnesium carbonate	0.070	0.030
Sodium chloride	0.071	0.181
Magnesium chloride	0.280	0.244
Potassium chloride	trace	trace
Sodium sulphate	0.090	0.120
Calcium sulphate	0.162	0.180
Ferrous carbonate	0.031	0.002
Silicic acid, organic matters, etc.	0.089	0.057
Total	1.043	0.954

The temperature of the different springs varies from 53.6° to 124° F.

A course at Rennes-les-Bains is recommended to those suffering from rheumatism, irritable nervous conditions, so-called scrofulous bone and joint affections, and enlarged glands, and also certain forms of cutaneous diseases. *T. L. S.*

REPTILES, POISONOUS. The popular mind, from the earliest period of historic time, has always turned with awe and wonder toward those mysterious gliding forms which hold in their economy the power of a swift and terrible death, a power which seems in no degree commensurate with the size of the destroyer; and this being the case, it is not to be wondered at that reptiles, particularly serpents, should have been objects of veneration and worshipped as gods, as they are even to the present day.

It would be foreign to the purpose of this paper to attempt a history of the serpent cult of all ages, its object being to call attention to certain poisonous forms, and to point out such remedial methods as may possibly mitigate the human suffering which they cause, or save the lives which they imperil.

In the subject matter which follows, no extended account of all the poisonous reptiles of the known world will be given, as this would require more space than could be allowed, but a list of our own species is furnished, with brief description of their appearance, characteristics, and the manner in which they destroy life by their bite. The physiological action of the different venoms will also be mentioned. Supplementary to this will be found brief notices of some of the more important forms of the old world.

For present convenient purposes the reptilian fauna of the United States may be considered as occupying an area bounded upon the north by the line of the Northern Boundary Survey, upon the east by the Atlantic Ocean, upon the west by the Pacific Ocean, and south by an imaginary line drawn from the southern extremity of the peninsula of California, extending eastward to the point of the Floridian peninsula.

In this vast extent of country naturalists have discovered no less than twenty-seven well-marked species of poisonous serpents, in four genera, and one poisonous lizard, the latter being the only one so far found upon the habitable globe. The first genus, *Crotalus*, contains fourteen species; the second, *Caudisona*, four species; the third, *Ancistrodon*, four species; the fourth, *Elaps*, five species; the lizard belonging to the genus *Heloderma*. The names of the serpents belonging to the genus *Crotalus* (the true rattlers) are as follows:

Crotalus lepidus Kennicott, Kennicott's Rattlesnake.
Crotalus pyrrhus Cope., Red Rattlesnake.
Crotalus Mitchelli Cope., Mitchell's Rattlesnake.
Crotalus cerastes Hallowell, Horned Rattlesnake, "Side-winder."
Crotalus tigris Kennicott, Tiger Rattlesnake.
Crotalus enyo Cope., St. Lucas Rattlesnake.
Crotalus horridus Linn., Banded Rattlesnake.
Crotalus adamanteus Beauvois, Diamond Rattlesnake.
Crotalus atrox Cope., Arizona Diamond Rattlesnake.
Crotalus scutulatus Cope., Scutulated Rattlesnake.
Crotalus lucifer Baird and Girard, California Rattlesnake.
Crotalus polystictus Cope., Spotted Rattlesnake.
Crotalus confluentus Say, Confluent Rattlesnake.
Crotalus molossus Baird and Girard, Black-tail Rattlesnake.

Belonging to the genus *Caudisona* are the following:
Caudisona rava Cope., Mexican Ground Rattlesnake.
Caudisona miliaria Linn., Southern Ground Rattlesnake.
Caudisona Edwardsi Baird and Girard, Sonora Ground Rattlesnake.
Caudisona tergemina Say, Black Rattlesnake, Prairie Rattlesnake, Massasauga.

The genus *Ancistrodon* (Moccasin and Copperheads) contains the following:
Ancistrodon piscivorus Lacépède, Water Moccasin.
Ancistrodon pugnax Lacépède, Texas Moccasin.
Ancistrodon contortrix Linn., Copperhead, Moccasin, Cottonmouth, Red-eye.
Ancistrodon atrofuscus Troost, Troost's Moccasin.

The genus *Elaps* (Vipers) contains:
Elaps fulvius Linn., Harlequin Snake, Viper.
Elaps tener Linn., Texas Harlequin Snake.
Elaps euryxanthus Kennicott, Sonora Harlequin Snake.
Elaps distans Kennicott, Florida Harlequin Snake.
Elaps tristis Baird and Girard, Tawny Harlequin Snake.

The poisonous lizard is known to science as:
Heloderma suspectum Cope., Gila Monster.

It should be stated that this list is in accordance with the "Check-list of North American Reptilia and Batrachia," Bulletin No. 24 of the National Museum, and is adopted, provisionally, by the authorities of that institution.

In view of the very general ignorance regarding the appearance of the venomous reptiles of this country, it seems desirable to give a brief account of their generic differences, as well as an account of the specific peculiarities of some of the well-known forms of the genera mentioned. *Crotalus, Caudisona*, and *Ancistrodon* belong to the family Crotalidæ, the remaining genus, *Elaps*, being a Colubrine serpent. The family characteristics of the Crotalidæ may be broadly stated as having erectable poison-fangs in front, few or no teeth in the upper jaw, a deep pit between the eye and the nostril; the general characteristics being as follows—the upper surface of the head is covered with small plates, scale-like in appearance, with a few larger ones in front; the tail terminates in a well-developed rattle; there is a deep pit between the eyes and the nostrils; the shields of the temporal and labial region are small and convex. Figs. 3231 and 3232, representing the head of *Crotalus atrox*, show very plainly the peculiarities named.

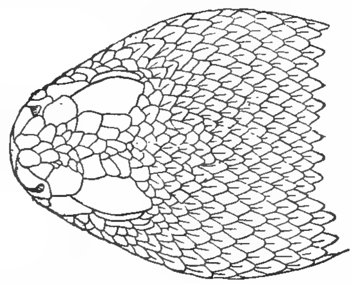

Fig. 3231.—Crotalus Atrox. View of head from above.

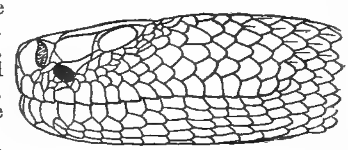

Fig. 3232.—The same, as seen in side view.

In *Caudisona* the upper surface of the head is covered with nine large plates, as is seen in the Colubrine snakes, and the tail terminates in a rattle, generally smaller than that of *Crotalus*. Figs. 3233 and 3234 represent the appearance of the head of *Caudisona tergemina*, and by comparing these figures with those of *Crotalus*, the difference in the head plates will be plainly seen. The pits anterior to the eye are also discernible.

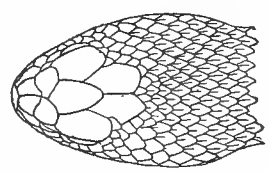

Fig. 3233.—Caudisona Tergemina. View of head from above.

In the genus *Ancistrodon*, the fangs are similar to those of *Caudisona*, and the ante-orbital pit is also present. There is no rattle on the tail, and the head is covered by either nine or eleven scales. Of the different species of this genus, one, *A. contortrix*, the Copperhead, is terrestrial, the others aquatic in their habits. Figs. 3235 and 3236 represent the head of *Ancistrodon contortrix*, the common Copperhead.

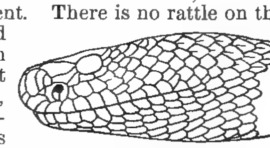

Fig. 3234.—The same, as seen in side view.

Elaps, the only venomous Colubrine serpent of North America, differs so materially from the other venomous serpents that a careful description seems necessary. The body, instead of being thick and stumpy, is slender and cylindrical, never exceeding four feet in length. The head is continuous with the body, not separated by a narrow neck as in *Crotalus*; it is subelliptical in shape, tapering forward, and is covered with plates. There is no ante-orbital pit. The mouth is not dilatable, and the upper jaw is furnished on each side with a small permanently erect fang, which is situated farther back than that of the Crotalidæ. The tail is slender and continuous with the body, and has no rattle. All the scales of the body are smooth, not keeled as in *Crotalus*. Figs. 3237 and 3238 represent the head of *Elaps fulvius*, the Harlequin Snake.

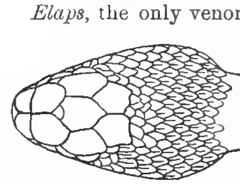

Fig. 3235.—Ancistrodon Contortrix. View of head from above.

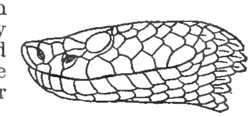

Fig. 3236.—The same, as seen in side view.

The colors of the different species of this genus are generally red for the body tint, with black, red, or yellow annulations, and their similarity to certain non-venomous snakes makes them particularly dangerous, as instances are on record of individuals having suffered in consequence of handling what were supposed to be innocuous serpents, but which really belonged to the genus *Elaps*.

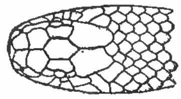

FIG. 3237.—Elaps Fulvius. View of head from above.

The genus *Heloderma* contains but one species, viz., *Heloderma suspectum*, the "Gila Monster," which may be described as a large stumpy lizard with a short tail, the whole reptile seldom exceeding eighteen inches in length. The head, sub-triangular in shape, is separated from the body by a constricted neck, and the whole of its upper surface is covered with ovoid tuberculated scales. The color is brownish-black, interspersed with yellowish spots. (See Plate XXVIII.) It is of interest because of the peculiar character of the teeth, which somewhat resemble those of poisonous serpents. Dr. Jacob Wortman, who has made a careful study of the dentition of this curious reptile, states as follows:

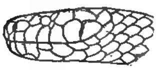

FIG. 3238.—Side view of the same.

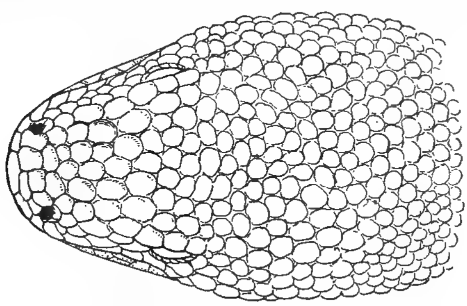

FIG. 3239.—Heloderma Suspectum, as seen from above.

"The form of the crown is that of a long, slender, sharp-pointed cone, curved inward and backward. The anterior outer surface of each tooth is marked by a well-defined groove, extending from the base to the apex. It is somewhat deeper at the base than at the summit, and is most distinct in the teeth of the lower jaw. The intervals between the bases of the teeth allow abundant room for the accommodation of poison-glands, the secretion of which is conveyed down the grooves and thus injected into the wound which the teeth inflict upon a prey."

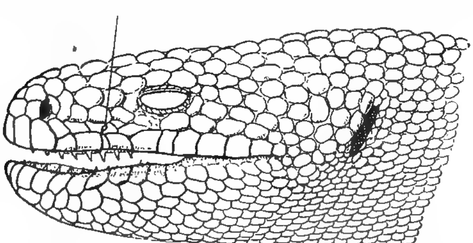

FIG. 3240.—The same; side view.

Whether true poison-glands actually do exist, has not yet been accurately determined. Figs. 3239 and 3240 will convey an excellent idea of the appearance of the head of the *Heloderma*, seen from above and in profile; the black line running vertically through the snout, having a hook at its lower end, is intended to show the lip drawn up, as under ordinary circumstances the teeth are concealed by the lips.

Having thus briefly considered the characteristics of the venomous reptiles, it may be proper to give a description of the mechanism which controls and operates the poison-fang apparatus of all our venomous serpents with the exception of *Elaps*, the account being substantially the same as was published by Dr. Elliot Coues and the writer as a result of their herpetological studies, a few years since, more modern researches having in no wise induced an alteration of the opinions then expressed.

In the production of the bite the active instruments are a pair of deciduous fangs, one on each side of the upper jaw, rooted in the maxillary bones, which bear few, if any, other teeth; but it should be mentioned as a matter of interest that, while in *Crotalus confluentus* the fangs are generally shed or pushed out of place at variable periods of time (probably in twelve months), in *Crotalus atrox*, a species common in the Sonoran region, this shedding or loss frequently fails to take place, and it is common to find, generally in the right side of the jaw of this species, two or more fangs in position. In one specimen, in possession of the National Museum, three are to be seen in position, and behind them are others well advanced in growth. The fangs vary in size, being sometimes three-fourths of an inch in length. They are somewhat conical and scythe-shaped, with an extremely fine point; the convexity looks forward, the point downward and backward. The fang is hollow for the transmission of the venom, but the construction of the tube is not as if a hole had been bored through a solid tooth. It is in effect a flat tooth, with the edges rolled over together till they meet, converting an exterior surface, first into a groove, finally into a tube. This is shown, on microscopic examination of a section of the tooth, by the arrangement of the dentine. Unlike an ordinary tooth, the fang is movable, and was formerly supposed to be hinged in its socket, since it is susceptible of erection and depression. But the tooth is firmly socketed, and the source of this movement is the maxillary bone itself, which rocks to and fro by a singular contrivance. The maxillary is a small, stout, triangular bone, movably articulated above with a smaller one, the lachrymal, which is itself hinged upon the frontal. Behind, the maxillary articulates with the palatal and pterygoid, both of which are of rod-like shape, and are acted upon by the spheno-pterygoid muscle, the contraction of which pushes them forward. This forward impulse of the palatal and pterygoid is communicated to the maxillary, against which they abut, causing the latter to rotate upon the lachrymal. In this rocking forward of the maxillary, the socket of the fang, and with it the tooth itself, rotates in such manner that the apex of the tooth describes the arc of a circle, and finally points downward instead of backward. This protrusion of the fang is not an automatic motion, consequent upon mere opening of the mouth, as formerly supposed, but a volitional act, as the reverse motion, namely, the folding back of the tooth, also is; so that, in simply feeding, the fangs are not erected. The folding back is accomplished by the ecto-pterygoid and spheno-palatine muscles, which, arising from the skull behind as a fixed point of action, in contracting draw upon the jaw-bones in such a way that the maxillary, and with it of course the fang, are retracted, when the tooth is folded back with an action comparable to the shutting of the blade of a pocket-knife. All the motions of the fangs are controlled by these two sets of antagonistic muscles, one of which prepares the fangs for action, while the other stows them away when not wanted.

The fangs, when not in use, are further protected by a contrivance for sheathing them, so that they rest like a sword in its scabbard. This is a fold of mucous membrane, the *vagina dentis*, which envelops the tooth like a hood, enwrapping its base, and slipping down over its length, partly as a consequence of its elastic texture, partly on account of its connections. Erection of the fang causes the sheath to slip off, like the finger of a glove, and gather in folds around the base of the tooth. This arrangement can readily be examined without dissection.

The poison-fluid is secreted in a gland which lies against the side of the skull, below and behind the eye, of a flattened oval shape, obtuse behind, tapering in front to a duct that runs to the base of the tooth. Without

going into the minute anatomy of the gland, it may be described as a sac, or reservoir, in the walls of which the numerous secretory follicles are imbedded; it is invested with two layers of dense, white, fibrous tissue, the outer of which gives off three strong ligaments that hold it in place. In a large snake, the entire gland may be nearly an inch long and one-fourth as wide, weighing, empty, ten or twelve grains, and having a capacity of ten or fifteen drops of fluid. There is no special reservoir for the venom, other than the central cavity of the gland. A certain dilatation of one portion of the duct, formerly supposed to be such a store-house, is due to thickening of its walls, without corresponding increase of capacity, resulting from muscular fibres which serve as a sphincter to compress the canal and prevent wasteful flow of the contents. There is further provision to this same end. When the tooth is folded back, the duct attached to its root is submitted to some strain, which pushes it against a shoulder of the maxillary bone, and tends to shut off the communication.

The injection of the venom, though to all appearance instantaneous, is a complicated process of several rapidly consecutive steps. Forcible voluntary closure of the jaws may always be, if desired, accompanied by a gush of the venom, owing to the arrangement of the muscles which effect such movement of the jaw. These are the *temporales*, one of the three of which is situated in such relation to the poison-sac that its swelling in contraction presses upon the receptacle and squeezes out the fluid. The force of ejection is seen when the serpent, striking wildly, misses its aim; under such circumstances, the stream has been seen to spirt five or six feet. A blow given in anger is always accompanied by the spirt of venom, even when the fang fails to engage, from whatever cause. But since this result does not follow upon mere closure of the mouth, it is probable that the two posterior temporals ordinarily effect this end, the more

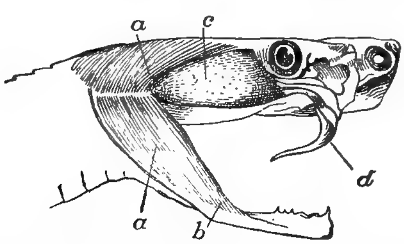

FIG. 3241.—Head of Crotalus. *a*, *a*, Anterior temporal muscle; *b*, point of insertion in the lower jaw; *c*, venom-gland; *d*, fang, partly erected.

powerful action of the anterior temporal (the one which presses upon the poison-sac) being reserved for its special purpose. There is one curious piece of mechanism to be noted here. Since the serpent snaps its jaws together in delivering a blow, the points of the fangs would penetrate the under jaw itself in case they failed to engage with the object aimed at, were there no contrivance for preventing such disaster to the snake. But there is a certain movement among the loose bones of the skull, perhaps not well made out, the result of which is to spread the points of the fangs apart in closure of the mouth, so that they clear the sides of the under jaw, instead of impinging upon it.

The complicated mechanism of the act of striking may be thus described: The snake prepares for action by throwing itself into a number of superimposed coils, upon the mass of which the neck and a few inches more lie loosely curved, the head elevated, the tail projecting and rapidly vibrating. At the approach of the intended victim, the serpent, by sudden contraction of the muscles upon the convexity of the curves, straightens out the anterior portion of the body, and thus darts forward the head. At this instant the jaws are widely separated, and the back of the head fixed firmly upon the neck. With the opening of the mouth the spheno-palatines contract, and the fangs spring into position, throwing off the sheath as they leap forward. With delivery of the blow and penetration of the fangs, the lower jaw closes forcibly, the muscle that executes this movement causing simultaneously a gush of venom through the tubular tooth into the wound. There are also some secondary actions, though all occur at the same moment. The mouth fixed at the wound drags upon it with the whole weight of the snake's body. This dragging motion is accompanied by contraction of the ecto-pterygoid and the spheno-palatine muscles, which ordinarily fold back

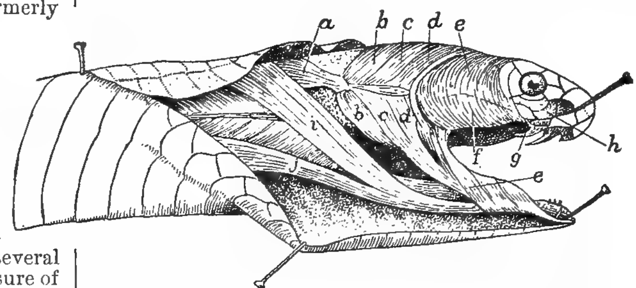

FIG. 3242.—Naja Tripudians. *a*, Is the trachelo-mastoid muscle; *b*, *b*, the digastric; *c*, *c*, the posterior temporal; *d*, *d*, the anterior temporal; *e*, *e*, the masseter; *f*, the poison-gland covered by masseter and fascia: *g*, poison-duct; *h*, maxillary bone; *i*, neuro-mandibular muscle; *j*, costo-mandibular muscle.

the tooth; but the fang being at this moment engaged in the flesh, the action of the muscles only causes it to bury itself deeper, and thus enlarge the puncture. The train of action seems to be, the reaching of the object, the blow, the penetration, the injection of the poison, and the enlargement of the wound. These actions completed, the serpent loosens its hold by opening the jaws, and disengages itself, sometimes not without difficulty, especially when the bitten part is small and the numerous small teeth have caught. The head is withdrawn, the fangs folded, the mouth closed, and the former coiled attitude of passive defence is assumed.

Fig. 3241, after Mitchell, represents the head of *Crotalus*, and shows the relation of the temporal muscles to the venom-gland, and the mode in which the pressure is exerted upon the poison-gland at the proper moment.

Fig. 3242, copied from Sir Joseph Fayrer's admirable work on the Thanatophidia of India, represents the head of *Naja tripudians*, the Cobra, the different muscles involved in the movements of the jaws and fangs being carefully delineated. By comparing this cut with Fig. 3241, it will be noticed that the fangs are fixed more anteriorly in the upper jaw than those of *Crotalus*, and the arrangement of the temporal muscles differs somewhat.

The mechanism of the jaw of *Elaps* resembles somewhat that of the Cobra, both reptiles belonging to the same class of poisonous colubrine serpents, the Elapidæ; but in *Elaps* the fang is permanently erect, the jaws be-

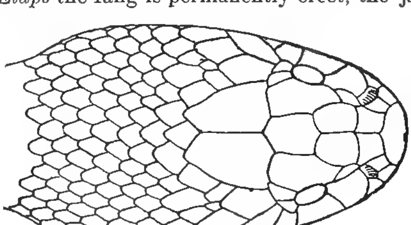

FIG. 3243.—Head of Naja Tripudians, as seen from above.

ing less dilatable than in most venomous species. This fact explains why it is that the death-dealing power of *Elaps* is more restricted than in other species.

Figs. 3243 and 3244 represent the head of *Naja tripudians* seen from above and in profile, and shows the characteristic appearance of the heads of the venomous colubrine serpents.

Cornell University Library

DIAMOND RATTLE-SNAKE. (*CROTALUS ADAMANTEUS.*)

It is a curious fact, that notwithstanding the knowledge possessed for ages regarding the poisonous effect of serpent venom, until within the last three centuries no attempt was made to study its peculiar physiological

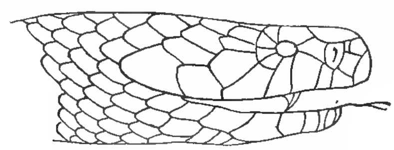

FIG. 3244.—The same, as seen in side view.

effects, the first writer on the subject being Francisco Redi, an Italian, who in 1664 published, at Florence, a paper upon the venom of the viper, entitled "Osservazione intorno alle Vipera," and this was followed, in 1767, by a work which may be considered classic, written by Felix Fontana, entitled "Richerche filosofiche sopra il veneno della Vipera," published in Lucca. In 1845, the naturalist, Prince Lucien Bonaparte, published a paper on the results of his analyses of viper venom, which was really the first scientific chemical study made. A number of other papers appeared from time to time subsequent to this, but it was not until 1860 that the most important work on serpent venom appeared. This was the "Study of the Venom of Rattlesnakes," by Dr. S. Weir Mitchell, of Philadelphia, and appeared as a volume of one hundred and seventeen quarto pages in the Smithsonian Contributions to Knowledge. In 1868, this distinguished physician supplemented his first paper by one in the *New York Medical Journal*, and in 1886, in collaboration with Dr. Edward T. Reichert, the great work entitled, "Researches upon the Venoms of Poisonous Serpents," appeared as No. 647 of the Smithsonian Contributions to Knowledge. It should not be forgotten that while our own countrymen were seeking to diffuse knowledge among mankind, the subject of serpent venom was being investigated by scientists abroad. In 1872 Sir Joseph Fayrer published a work on the venomous serpents of India; Dr. Lauder Brunton and himself published in the same year an admirable physiological study of venoms. In 1883, appeared a comparative study of the venoms of the colubrine and viperine snakes of India, by Dr. A. J. Wall; nor should the work on antidotes, by Vincent Richards, be forgotten.

The physical appearances of all serpent venom are nearly alike, varying in color from pale amber to deep yellow when fresh, although it has been stated that occasionally the *Cobra* venom is colorless; and this finds its analogy in the venom of our own *Elaps*, which has been seen on one occasion to lack color. In the desiccated condition venom appears as yellow particles, semi-transparent, and remains unchanged for long periods of time. It is equally virulent whether dry or preserved in alcohol or glycerine, Dr. Mitchell having in his possession a glycerine solution which was poisonous after twenty years' preservation. For a full description of the microscopic appearance and the changes which venom undergoes the reader is referred to the admirable study by Mitchell and Reichert already mentioned. So far as the chemistry of venom is concerned, the presence of alkaloids and ptomaïnes has long been suspected, but up to the present time they have been sought for in vain; but Mitchell and Reichert have succeeded in isolating certain principles belonging to two classes, the former termed globulins, the other peptones. To the first belong complex substances which they call *water-venom-globuline*, *copper-venom-globuline*, and *dialysis-venom-globuline*, these names indicating the chemical processes by which they have been separated. The venom peptone is found in a solution of the poison after boiling, which coagulates the albuminous principles, or it may be prepared by dialysis. In the cobra venom Drs. Mitchell and Reichert have been able to isolate two proteids which are similar in character to those found in the venoms of *Crotalus* and *Ancistrodon*, which are a globulin and peptone-like principle. From a careful series of analyses it has been found that the venom of *Crotalus adamanteus* contains 24.6 per cent. of globulins, that of *Ancistrodon* 7.8 per cent., and that of the cobra 1.75 per cent. Serpent venom has been subjected to the action of various agents with a view to determine the effects in reducing its toxic power. Dry and moist heat have little if any effect, but prolonged boiling seems to reduce the poisonous quality, owing to the fact that the peptone is converted into a coagulable albuminoid which is not destructive to life. The addition of a sufficient quantity of caustic potassa to a solution of venom, absolutely destroys the toxic power, and caustic soda appears to have the same effect. A number of other substances have been employed, but space will not admit of a further consideration of the results attained; but it may be stated as a matter of interest that a solution of the permanganate of potassa is said to be an absolute chemical antidote to serpent venom.

Much might be said of the effects of venom, but a brief notice seems all that is necessary, as the subject has been most elaborately discussed by the authors already quoted. *Crotalus* poison, if swallowed, is harmless, as it is not absorbed by the healthy mucous membrane, or because it undergoes some change in the progress of digestion which makes it harmless; but Fayrer has found that the ingestion of cobra poison by mammals does produce death. When venom is applied to serous surfaces absorption takes place most rapidly, and hæmorrhagic patches occur with surprising celerity. According to Mitchell, after the hypodermic injection of venom, the following pathological appearances may be noticed: "There appears a swelling at the point of injection, with intense violet-black discoloration of the skin which gradually extends over an area of several square inches. On making an incision into the tissues in the immediate neighborhood of the injection, they are found to be soaked with extravasated blood. This is often all that is visible if death has occurred soon, but if it has been postponed for a short time, then, in tissues distant from the place of injection, extravasations to a smaller extent are always found. Most pronounced and most frequent are the ecchymoses below serous membranes (subpleural, subperitoneal, and subpericardial); in fact the whole organism is deeply affected, the tissues being congested and presenting a much darker appearance than normal. The blood does not seem to coagulate readily within cavities or interstices of the body unless death follows almost instantaneously. In cases which live longer the blood remains constantly in a liquid state, or coagulates imperfectly, and then only after being exposed to the air, resembling in this particular the state of that fluid observed in conditions of asphyxia."

As the valuable work of Mitchell and Reichert is not generally available to the public or practitioners of medicine, it may be proper to give in their own words a summary of the conclusions arrived at, as a result of their most valuable and careful studies:

"1. Venoms bear in some respects a strong resemblance to the saliva of other vertebrates.

"2. The active principles of venom are contained in its liquid parts only. The solid constituents, such as we observed suspended in the poison, consist of epithelium cells, some minute rod-like animal organisms and micrococci, etc., which, when separated from the liquid, fresh venom by means of filtration and well washed by water, are harmless. Micrococci are constantly present in fresh venom, but have nothing to do with its virulence.

"3. Venoms may be dried and preserved indefinitely in this condition, with but very slight impairment of their toxicity. In solution in glycerine they will also probably keep for any length of time.

"4. There probably exist in all venoms representatives of two classes of proteids, *globulins* and *peptones*, which constitute their toxic elements; the former may be represented by one or more distinct principles.

"5. When venom is taken into the stomach in the intervals of digestion, enough of the poison may be absorbed to produce death, especially in the case of those venoms which contain a larger proportion of the more

dialysable peptone; but during active digestion the venom undergoes alteration, and is rendered harmless.

"6. Potassic permanganate, ferric chloride in the form of the liquor or tincture, and tincture of iodine seem to be the most active and promising of the generally available local antidotes.

"7. Venom exerts a powerful local effect upon the living tissues, and induces more rapid necrotic changes than any known organic substance. It causes œdema, swelling, attended with darkening of the parts by infiltration of incoagulable blood, breaking down of the tissues, putrefaction, and sloughing.

"8. It renders the blood incoagulable.

"9. When brought in contact with a vascular tissue of a warm-blooded animal, it produces such a change in the capillary blood-vessels that their walls are unable to resist the normal blood-pressure, thus allowing the blood-corpuscles to escape into the tissues. These lesions are, however, not analogous to those of inflammation, since in the latter process it is principally the white blood-corpuscles which emigrate from the vessels, and the blood is highly coagulable, while here the blood exudes *en masse*, and coagulates with difficulty, if at all. Free access of air (probably of oxygen) appears to lessen the virulent effects. The mesentery exposed to air, and on which the venom is merely brushed, endures the venom longer and in much larger quantities than when the poison is injected into the unopened and uninjured peritoneal cavity, or when directly thrown into the blood. There may be here, also, a question of temperature and other conditions.

"The following facts, as elicited in these investigations, seem to be sufficient to explain the mechanism of the hæmorrhages: The blood-pressure has been shown to play a most important part; a watery salt solution substituted for the blood does not extravasate, hence blood seems to be necessary; there always occur molecular changes in the blood-vessel walls from the effect of venom. That blood-pressure is an important factor has been established by the observation that the hæmorrhages, as a rule, occur first in the capillaries which are immediately next to, or nearest, the large blood-vessels. The hæmorrhages take place soonest where the force of the blood-current is first felt and cannot be sufficiently resisted, and in no case do hæmorrhages seem to originate from vessels with strong walls, like the arterioles or veins. Cutting off the circulation of a part, as, for instance, by ligation of the vessel of the mesentery, destroys the blood-pressure, and, as a consequence, the hæmorrhages are so slight as scarcely to be seen by the naked eye, though venom was freely applied. Finally, the colloid, softened, diffluent condition of the red corpuscles must inevitably facilitate extravasation. It is impossible to have seen numerous cases of venom-poisoning without noting a variety of symptoms often abrupt or unexpected. These often are due, as Dr. Mitchell long since pointed out, to accidental hæmorrhages into the brain, kidney, and heart tissues. They explain much which might otherwise seem inscrutable, and serve sometimes to give a marked individuality of symptoms to cases which survive long.

"10. Among the most remarkable effects of venom is that upon the red blood-corpuscles. These bodies undergo substantial modifications, *i.e.*, they lose their biconcave shape, become spherical and softened, and fuse together into irregular masses, acting like soft, elastic, colloid material. This jelly-like condition of the corpuscles is, no doubt, doubly important: in connection with the extravasation of the blood, and in its probable interference with the normal respiratory functions of the blood-cells.

"11. The direct action of venom upon the nervous system, save as concerns the paralysis of the respiratory centres, is of but little importance.

"12. The alterations in the pulse-rate are dependent chiefly upon two antagonistic factors which are active at the same time, the one tending to increase the rate, and the other to diminish it. The former is found in the increased activity of the accelerator centres, and the other in a direct action on the heart. When we have the action of the accelerator centres removed by isolation of the heart from any centric influence, we almost invariably find a diminution of the heart-beats. Occasionally after this operation the pulsations are increased, but this alteration is attended, as in the case of the diminution of the pulse, by feeble heart-beats, and, accordingly, is but a manifestation in another way of a depressed condition of the heart.

"13. The variations in arterial pressure are due chiefly to three causes—depression of the vaso-motor centres, depression of the heart, and irritation, and consequent constriction or blocking up, of the capillaries. It seems not improbable that all of these are consentaneously active, and it therefore follows that such alterations are dependent upon the relative degree of power exerted by any one of these factors. Our results indicate that the profound primary fall of arterial pressure is chiefly due to depression of the vaso-motor centres, and is in part cardiac, that the subsequent recovery is capillary, while the final fall is cardiac. The initial fall does not continue, because the constriction of the capillaries is, for a time at least, capable of compensating the depressed action of the central organ of circulation.

"14. The respirations are primarily increased and secondarily diminished. Here again we have two antagonistic factors at work together, one tending to increase and the other to diminish the rate. The former is an irritation of the peripheries of the vagi nerves, and the latter a depression of the respiratory centres; whether we have an increase followed by a decrease, or a decrease from the first, will depend upon the relative intensity of the action of the venom on these two parts. When the action of the venom is sufficient to profoundly depress the centres the excitation of the peripheries may prove futile.

"15. Death in venom-poisoning may occur through paralysis of the respiratory centres, paralysis of the heart, hæmorrhages in the medulla, or possibly through the inability of the profoundly altered red corpuscles to perform their functions. There can be no question, however, that the respiratory centres are the parts of the system most vulnerable to venom, and that death is commonly due to their paralysis.

"A general survey of the chief physiological actions of venoms leads us to believe that the most important effects are upon the respiratory and circulatory apparatuses, and that in the production of these results antagonistic factors are at work, so that we sometimes have observations which seem directly contradictory. When it is remembered that there are two classes of poisons in venoms, that each class possesses certain distinguishing physical, chemical, and physiological differences, although closely related, it is easy to conceive of the cause of the existence of antagonistic actions and the necessarily varying results.

"A comparative study of the actions of the *globulins* and *peptones* indicates that the *globulins* produce swelling and blackening of the parts by infiltration of incoagulable blood; they are the more potent in producing ecchymoses, in destroying the coagulability of the blood, in modifying the red corpuscles, and in the production of molecular changes in the capillary walls; their action on the accelerator centres of the heart is more notable than that of the *peptones*, hence they are more active in causing the increased pulse-rate; they exert, too, a more marked action on the vaso-motor centres in producing the primary fall of pressure, and are the greater depressants of the heart; they also act more powerfully upon the respiratory centres to paralyze them. The *peptones* are more active in the production of œdema, in the breaking down of the tissues, in the production of putrefaction and sloughing; they have little power to produce ecchymoses, to prevent coagulation, or modify the capillary walls or the blood-corpuscles; they have less tendency to accelerate the pulse; they tend to increase the blood-pressure by irritating the capillaries, and are the principal factors in exciting the peripheries of the vagi

nerves in the production of the increased respiration-rate.

"A knowledge of these peculiarities in the actions of *globulins* and *peptones*, coupled with the fact that the two classes exist in different proportions in the various species of venoms is of great importance in explaining the diverse pathological appearances in cases of poisoning in different kinds of snake-bite, and suggests immediately the cause of the frightful local changes which are seen after the bite of the Crotalidæ, but scarcely at all in cobra-poisoning. It must not, however, be supposed that the peptones or globulins, for instance, are absolutely identical physiologically in every venom, as they are probably modified physiologically as well as chemically, although we do not doubt that on the whole the type of action is carried throughout all species. Cobra venom does not produce the marked lesions of crotalus-poisoning because it is so lacking in globulins; it is weak in the production of the local swelling and blackening of the parts, of the ecchymoses, of the altered corpuscles, and of the non-coagulability of the blood; but the effects of cobra venom are closely in accord with the actions peculiar to peptones. The peptone of cobra seems to have a more decided power in producing convulsions than that of the rattlesnake.

"The fact that the active principles of venom are proteids, and closely related, chemically, to elements normally existing in the blood, renders almost hopeless the search for a chemical antidote which can prove available after the poison has reached the circulation, since it is obvious that we cannot expect to discover any substance which, when placed in the blood, will destroy the principles of venom without inducing a similar destruction of vital components in the circulating fluid. The outlook, then, for an antidote for venom which may be available after the absorption of the poison, lies clearly in the direction of a physiological antagonist, or, in other words, of a substance which will oppose the actions of venom upon the most vulnerable parts of the system. The activities of venoms are, however, manifested in such diverse ways, and so profoundly and rapidly, that it does not seem probable that we shall ever discover an agent which will be capable at the same time of acting efficiently in counteracting all the terrible energies of these poisons."

With regard to the poisonous effects produced by the venom of the *Ancistrodons* (Moccasins and Copperheads), the reader is referred to an article by the writer which appeared in the *American Journal of the Medical Sciences*, Philadelphia, April, 1884, in which special attention is called to the recurrence of symptoms of poisoning after snake-bite; this recurrence seems to be confined to cases in which individuals were bitten by the serpents of the genus named. In the *Medical News*, Philadelphia, 1887, i., p. 623, the writer, after carefully watching the two cases mentioned in the former paper during a period of nearly three years, published a short paper upon the "Recurrence of Symptoms of Poisoning after Snake-bite," in which the results of the examination of the patients and the recurrent symptoms are fully set forth.

With regard to the poisonous lizard, *Heloderma suspectum* (Gila Monster), there is a mass of conflicting evidence as to its toxic power. The Mexicans have long looked upon it as dangerous, but other perfectly harmless lizards also share in this evil reputation. Surgeon B. J. D. Irwin, U. S. A., experimented many years since, while on duty in New Mexico, with the Gila Monster, and concluded that it was harmless, and a number of persons have been bitten, within the writer's knowledge, without evil results. In fact, in New Mexico and Arizona the reptile is kept as a domestic pet, and handled with great carelessness. Opposed to the view of its non-dangerous nature are the facts that persons have undoubtedly perished from its bite, the writer having in his possession the affidavits of two respectable individuals who witnessed a death, and the experiments of Mitchell and Reichert, which conclusively show that the saliva-like fluid from the mouth of the *Heloderma*, when injected beneath the skin of an animal, produces fatal results with great rapidity.

These investigators obtained the fluid by provoking the animal to bite on a saucer edge, and after it had held on for a few moments a thin fluid like saliva was observed to issue from the lower jaw. This fluid was distinctly alkaline, differing in this respect from the venom of all serpents, which is acid. The first experiment made by these gentlemen was as follows: "About four minims were diluted with one-half cubic centimetre of water, and thrown into the breast-muscles of a large, strong pigeon at 4.23 P.M. In three minutes the pigeon was rocking on its feet and walking unsteadily. At the same time the respiration became rapid and short, and at the fifth minute feeble. At the sixth minute the bird fell in convulsions, with dilated pupils, and was dead before the end of the seventh minute. The first contrast to the effects of venom was shown when the wound made by the hypodermic needle was examined. There was not the least trace of local action, such as is so characteristic of the bites of serpents, and especially the Crotalidæ. The muscles and nerves responded perfectly to weak induced currents, and to mechanical stimuli. The heart was arrested in the fullest diastole, and was full of firm, black clots. The intestines looked congested. The spine was not examined."

Subsequent experiments with rabbits and frogs produced like results, the conclusions of the authors being, "That the poison of *Heloderma* causes no local injury. That it arrests the heart in diastole, and that the organ afterward contracts slowly—possibly in rapid rigor mortis.

"That the cardiac muscle loses its irritability to stimuli at the time it ceases to beat.

"That the other muscles and the nerves respond readily to irritants.

"That the spinal cord has its power annihilated abruptly, and refuses to respond to the most powerful electrical currents."

It should not be forgotten, however, that Dr. Sternberg and Professor Gautier have proved that human saliva may produce death in rabbits and pigeons, the latter observer considering the venomous properties due to normal ptomaines or animal alkaloids.[1]

It is by no means uncertain that in the near future it may be shown that the saliva of other reptiles possesses poisonous qualities, especially in such genera as *Siren*, *Pseudobranchus*, *Necturus*, *Amphiuma*, *Murænopsis*, and *Menopoma*, which in the Southern States are popularly supposed to be able to destroy life by their bite.

The *symptoms* produced in man by the bites of poisonous serpents possess a certain degree of similarity, their gravity depending largely upon the size of the reptile and the amount of venom injected into the wound. In case the serpent had repeatedly used its fangs and exhausted the supply of venom, dangerous symptoms would be less pronounced. Briefly, they may be stated as follows: After the puncture, at first the pain is slight in the part; this gradually increases along the line of the lymphatics, with nausea; bleeding takes place, with rapid tumefaction and discoloration in the vicinity of the wound. The pulse is feeble and fluttering, and in some cases, when an overwhelming dose of the venom has been received, the action of the heart is almost paralyzed. If remedial means are not employed there is exaggeration of all the symptoms mentioned, with incontinence of urine and involuntary passage of fæces, delirium, coma, and death, which may occur within a few hours.

These symptoms may be immediate or delayed, as in the case of the photographer bitten by a copperhead, and reported by the writer, as in this individual several days elapsed before any real suffering commenced, the entire duration of the poisonous symptoms lasting from May 30th until late in August.

Regarding the *treatment* of poisoning by serpent venom, many plans have been suggested, and hundreds of remedies employed with varying success; but to an intelligent observer of such an accident the indication would doubtless be to prevent the entrance of the poison

into the general circulation by means of a ligature or bandage, which should not be narrow, but quite broad, and applied above the bite or between it and the heart, it being, of course, understood that these remarks, so far as ligatures are concerned, apply to wounds of limbs. The bite or bites should then be laid open by crucial incision, care being taken not to injure blood-vessels, and suction should be made, either by the mouth (in case no abrasions of the mucous surface exist), or by cupping; this latter procedure may be made by means of surgical cups if available, by a small tumbler or wineglass from which the air has been exhausted by burning a small quantity of alcohol or spirits therein, or by means of an ordinary wide-mouthed bottle or can, in which boiling-hot water should be poured and quickly emptied. Alcoholic stimulants or digitalis should be given by the mouth, or hypodermatically if nausea exists, to keep up the flagging heart, and the band should be loosened for a few moments at a time in order that only a small quantity of the venom shall enter the circulation. This process should be repeated, and the pulse will indicate when the proper amount of stimulation has been reached. It is not necessary to produce drunkenness, as it is believed that in some cases, especially of children, death has resulted not from the snake venom, but from lethal doses of alcohol. The mountaineers of the West attach much virtue to the flashing of a quantity of gunpowder over the bite, this, with cataplasms of tobacco and unlimited whiskey, constituting almost their entire pharmacopœia.

Within a few years, however, the attention of those interested in the subject of serpent-bite has been called to the elaborate experiments of Dr. J. B. de Lacerda, Director of the Physiological Laboratory of the National Museum of Rio Janeiro—a study followed with most conscientious care, and one which seems to show that there exists a most potent chemical antidote to serpent venom. His researches commenced in 1872, and in 1881 he announced to the French Academy of Sciences that he had made a valuable discovery. Alluding to the inefficiency of the various so-called antidotes, he stated that he found that a solution of potassium permanganate was an absolute antidote. The venom used was from the *Bothrox*, a very well known and venomous serpent of Brazil, and it was obtained by forcing the reptile to bite upon cotton-wool. The quantity thus procured was dissolved in eight or ten grammes of distilled water, and a certain amount of the solution was injected into the leg of a dog. In a few minutes after, the same quantity of a filtered one per cent. solution of potassium permanganate was injected into the wound. Next day the animal was perfectly well, with the exception of a slight local irritation. The poison injected in other animals, without the subsequent use of the permanganate, produced grave and dangerous symptoms. The venom was also injected into a vein, and the permanganate proved equally efficacious in preventing poisonous symptoms; and in some cases, before using the antidote, the symptoms of poisoning were allowed to continue for quite a lengthy period; and out of thirty experiments all were successful with but two exceptions. It is proper to add that many of Lacerda's experiments were performed in the presence of the Emperor of Brazil, and other scientific individuals. Lacerda's experiments with the permanganate of potassa have been repeated by a number of observers with varying results, but in view of the very positive statements made by him it would appear that the permanganate should be given a trial. It should be used in the form of a one per cent. solution in water, and injected into the bites made by the teeth of the serpent.[2]

The writer, while sojourning among the Moqui Indians of Arizona, at the time of their celebrated "snake-dance," was shown the so-called antidote which they employ in case a dancer is bitten; it is a pale, dirty-green fluid, without odor, and slightly bitter taste, but its composition could not be ascertained, only two individuals in the tribe knowing how to prepare it. This preparation is used, mixed with saliva and the charcoal of piñon nuts, to smear the bodies of those Indians who are to participate in the dance, and after it is finished copious draughts of it are swallowed, which produce prompt emesis. In case one is bitten, which happens occasionally, the wound is immediately sucked, some of the antidote rubbed into the wound, and a large quantity swallowed. During the last ten years, in which period five dances have occurred, but one individual has perished from snake-bite; and this is the more surprising when the fact is made known that the salient feature of the dance consists in the dancer holding one or two rattlesnakes in the mouth. The writer saw two individuals bitten, both by harmless snakes. Unfortunately for science, no opportunity was afforded to test the permanganate solution, which had been prepared and was on hand for use should occasion offer.

After the subsidence of acute symptoms of snake-bite, the others would have to be treated according to the general indications.

Considering the number and wide distribution of venomous serpents in the United States, and in view of the fact that no absolutely reliable plan of treatment is known, it is surprising that so few individuals lose their lives from snake-bite. That the rattler is still numerous in certain portions of our country, the following statement will show: In 1876, Lieutenant Morrison, U. S. A., encountered in New Mexico a colony of *Crotalus confluentus*, of which not less than from three to five hundred were seen during the occupation of a hill as a topographical station, and of which seventy-nine were killed in less than one hour; and Professor J. A. Allen reports that during the Yellowstone Expedition of 1872, not less than two thousand were killed.

With reference to the subject of antidotes, mention may be made of a remarkable work, published by Boericke & Tafel in 1872, in which the author endeavors to prove that the galls of serpents are antidotal to their bite. In preparing the gall for use, one drop is added to ten drops of pure alcohol, and the mixture is allowed to stand for a few days, at the expiration of which period the supernatant liquid is poured off and carefully preserved in a well-corked vial. In ordinary cases of bite, five or ten drops of this tincture are added to half a tumbler of water, and a tablespoonful of the mixture is administered every five, ten, fifteen, or twenty minutes, according to the violence of the symptoms. In addition to the internal use of the gall, a cruciform incision is made over the wound, and a few drops of the preparation are dropped in. Unfortunately the value of this so-called antidote depends entirely upon the statement of its discoverer, and it is believed little credence can be attached to his published results, as Sir Joseph Fayrer, following instructions received from the author, failed utterly to neutralize the poisonous effects of the venom of *Cobra* and *Bungarus*, using the gall as directed.

The popular mind has ascribed to certain serpents properties, venomous and otherwise, which they really do not possess, and it is thought a correction of these errors may perhaps serve a useful purpose.

In some parts of the United States is found a snake belonging to the genus *Heterodon*, which inspires as much fear as the rattlesnake; in fact, the species known as *Heterodon niger* is called in Virginia the "black rattlesnake," although the want of a rattle should prove the name a misnomer. This reptile has a broad, flat head, with a somewhat constricted neck, a stout body, and a short stumpy tail, and when captured it hisses fiercely, expands the cervical ribs, and presents a very pugnacious appearance. The coloration of one species is somewhat like *Crotalus confluentus*, and, if the mouth is examined, in the upper jaw will be found fang-like teeth, which have given origin to the generic name, which means "different or dissimilar teeth." These teeth are not grooved, and are not connected with anything resembling a poison-sac. Notwithstanding its dangerous appearance it is absolutely harmless, and can scarcely be provoked to bite. Not long since, the writer had forwarded to him, by an intelligent gentleman living in the South, one of these snakes, which was declared to be one of the most poisonous known to the region; it proved to be *Hetero-*

don platyrhinus. The common names for this serpent are "puff-adder," "hog-nosed snake," "sand-viper," etc.

Next to the almost universal belief regarding *Heterodon*, is a similar opinion about the so-called water moccasin, *Tropidonotus sipedon*, and one of the old writers, in a history of Virginia, describes this serpent so that no doubt as to its identity can exist, and then gravely states that an Indian was severely bitten by one, but by the application of proper remedies finally recovered. This serpent, as is well known to naturalists, resembles the poisonous species *Ancistrodon piscivorus*, and as both are found in and about watery places, it is not surprising that their properties should have been confounded. In addition, *Tropidonotus* is a very pugnacious individual, and will bite fiercely if opportunity offers, especially if it has not been handled—in fact, even then, if roughly seized. Some time since, the writer had occasion to remove a small sebaceous tumor from below the angle of the jaw of a fine female *Tropidonotus* belonging to the National Museum, and after the operation, as it had lost a considerable amount of blood, and seemed very weak, it was placed in the pond of water in the rotunda of the Museum. Desiring to exhibit it to a friend, it was removed from the water, when it struck fiercely at the hand, throwing its upper jaw back as the venomous serpents are in the habit of doing, and at the third stroke succeeded in fixing its teeth near the base of the thumb. The pain was trifling, and had it not been for the somewhat free bleeding, an injury would hardly have been suspected; no evil consequences resulted, nor have any ever occurred, as the writer has been bitten several times by this species.

The difference in the appearance of the head between the true moccasins and the so-called water moccasin is very marked. In the former the plane surface of the head may be said to roughly resemble a triangle, the snout representing the apex, the angle of the jaws the base, the neck being narrow behind. In this species the pit between the eye and nostril is well marked. In the harmless species the head is hardly separated from the body by a constricted neck; it is rounded, and the expanse of the angles of the jaw not so well marked. It has, however, when coiled up, a very vicious appearance, and resembles greatly a venomous snake.

One of the most curious myths in regard to serpents is that of the "hoop-snake" or horn-snake, which is thus described by a recent writer: "The horned snake is the last of the poisonous serpents, and is a great curiosity. Instead of in the head, it carries its weapon in its tail, which has a horny appearance, is shaped like a cock's spur, and is from an inch to an inch and a half in length. This tail has a cavity, inclosed in which is a sharp needle-like sting, growing from the extreme point of the tail. The snake puts the end of the tail in the mouth, thus forming a hoop, and rolls forward until within striking distance, when it slips the tail from the mouth and strikes with considerable force tail foremost. The sting produces about the same effect as the sting of the adder. The horned snake is about three feet long when full grown, rather dark in color, and is oviparous. They are very scarce and seldom seen."

What is known as the horned snake in the West and Southwest is the *Farancia abacura*, of which the head and back are bluish-black above, and which has subquadrate red spots on the flanks. Its abdomen is rosy-red, with transverse or alternating bluish-black irregular spots. How or why it should have acquired the unenviable reputation it possesses, at present is unknown, for it is one of the most harmless and gentle of all snakes. That its tail ends in a horny tip is true, but the "bull-snake" of California, *Pityophis bellona*, has a similar horny tip, but neither the one nor the other ever uses it for defensive or offensive purposes. In some of the Southern States the grass lizard, *Opheosaurus ventralis*, is also called the horn snake.

Another serpent about which a curious superstition prevails is the "coach-whip snake," and lying at full length in the road it seems worthy of its popular name. To naturalists it is known as *Bascanium flagelliforme.* The anterior fourth of the body is a deep brownish-black color, which gradually becomes lighter until near the posterior part, where it is of a yellowish-gray. This coloration, in connection with a peculiar arrangement of the scales, gives it a very whip like appearance, the dark part of the body being the handle, the lighter the lash. This reptile, in the South, has long been a terror to the colored population, and many are the stories related of how drunken and belated negroes have been found dead in the road, whipped to death by the coach-whip snake. Perhaps it would not be unfair to say that it is probable that this tradition was encouraged during ante-bellum days as a wholesome corrective to the night-prowling propensities of the slaves. This serpent is very graceful, and it may be imagined that if held, provoked, or irritated, it might, in its efforts to escape, switch fiercely with its long tail and body; but as for its being able to seize a person and whip him to death, the tradition must be consigned to limbo, with others of similar nature. From the somewhat fragile nature of the ligamentous attachments of the spinal vertebræ of the reptile, it is more likely that the snake would stand a better chance of breaking its back than of inflicting serious injury.

Of all the habitable regions of the globe, the empire of India is without doubt the one in which the greatest destruction of human life takes place from the bites of venomous serpents, and it may be interesting to briefly consider some of the well-known species which contribute to the fearful result. Sir Joseph Fayrer states that the average mortality from serpent-bite is fully twenty thousand annually, and in 1869, care was taken to obtain, officially, returns of cases, which showed that out of a population of 121,000,000, in an area embracing only one-half of the peninsula of Hindostan, the deaths were 11,416, or nearly one in ten thousand. These deaths were caused, as nearly as could be ascertained, as follows: *Cobra*, 2,690; *Krait* (*Bungarus ceruleus*), 359; other snakes 839; unknown snakes, 6,922; no details, 606; total, 11,416. The British government recognizing the importance of destroying venomous snakes, paid a bounty, in 1880, for the enormous number of 212,776, and in 1881, for 254,968.

Superior in venomous properties are the *Elapidæ*, of which several genera are common in India; *Najidæ*, or snakes with hoods, or dilatable hoods, or dilatable necks; and the *Elapidæ*, without hoods. *Najidæ* contains two genera, *Naja* and *Ophiophagus*, and in *Elapidæ* are *Bungarus*, *Xenurelaps*, and *Callophis*. The characteristics of the family are a cylindrical body, a rather short and tapering tail, and a lateral nostril. The poison-fang has a mark in its convexity indicating the groove, differing in this respect from the poisonous water-snakes, *Hydrophidæ*, in which it is quite open. At the head of the list should be placed the *Cobra*, or *Cobra di capello*, *Naja tripudians*, of which there are a number of well-recognized varieties, all of them possessing most deadly properties. The largest *Cobra* seen by Fayrer had attained a length of five feet eight inches, and measured six and one-fourth inches in circumference, and a fowl bitten by it perished in one minute. The color of the *Cobra* varies from dark olive or black, to pale chocolate or yellow, and the markings on the hood vary greatly in the different varieties. All of them possess the hood, and never bite without expanding it, and, unlike the rattlesnake, the body is not coiled, the lower two-thirds remaining upon the ground while the anterior third is raised, the head oscillating from side to side with wary caution in preparing to attack. They are good climbers and take readily to water, although essentially terrestrial in habits. *Ophiophagus elaps* is the only representation of its genus, and is probably even more formidable than the *Cobra*, as it attains a length of from twelve to fourteen feet. It has no hood and is exceedingly aggressive. The coloration varies greatly, but the general tint may be described as olive-green above, the scales edged with black, the trunk having on it numerous alternate black and white bands converging toward the head. To the Bengalese it is known

as the "shell breaker," and its habits are largely arboreal, although it takes to the water. Dr. Carter relates the following anecdote regarding its fierceness. "An intelligent Burman told me that a friend of his one day stumbled upon a nest of these serpents and immediately retreated, but the old female gave chase. The man fled with all speed over hill and dale, dingle and glade, and terror seemed to add wings to his flight, till reaching a small river he plunged in, hoping he had then escaped his fiery enemy; but lo! on reaching the opposite bank up reared the furious *Hamadryad*, its dilated eyes glistening with rage, ready to bury its fangs in his trembling body. In utter despair he bethought himself of his turban, and in a moment dashed it upon the serpent, which darted upon it like lightning, and for some moments wreaked its vengeance in furious bites; after which it returned quietly to its former haunts." This serpent, as its name implies, devours other snakes, but it doubtless also feeds upon birds and small animals.

The genus *Bungarus* contains two Indian species, *B. fasciatus* and *B. cæruleus*, known to the natives as *Kraits*, and these serpents, next to the *Cobra*, are probably the most destructive to human life in India. The coloration of *Bungarus* is uniform blackish-brown, the head being white in young individuals, although as in the other serpents there is some variation of tint. In *B. fasciatus* the triangular shape of the body and sharp dorsal ridge are especially noticeable. *Xenurelaps bungaroides*, the only known representative of its genus, resembles greatly the *Bungarus;* but little is known as to its habits.

The genus *Callophis* contains a number of species, but from their small size and diminutive fangs they are probably not so dangerous to human life as the other venomous serpents.

Belonging to the viperine serpents is the terribly venomous *Daboia russelli*, which is of a light chocolate color, with black white-edged rings, and which also shows many variations of tints. It is most justly dreaded, for with its long, movable fangs it produces deep mortal wounds. It is terrestrial in its habits, and lives upon small animals. Dr. Imlach states that it is not uncommon to find two fangs on both sides of the upper jaw.

There are a number of other genera of poisonous serpents in India, such as *Echis, Trimeresurus, Peltopelor, Halys*, and *Hypnale*, which resemble the North American *Crotalidæ* in having the ante-orbital pit, and are without rattles; but space will not admit of a consideration of their peculiarities.

The most interesting of all venomous serpents are probably the sea-snakes, which inhabit the estuaries and tidal streams, and are known to naturalists as the *Hydrophidæ*. They have a wide geographical distribution, being found in the Indian and Pacific Oceans from Madagascar to the Isthmus of Panama; Günther says they are most numerous in the Eastern Archipelago and in the seas between Southern China and North Australia. The sea-snakes vary greatly in form, some of them attaining a length of five feet; the body is elongated, and in some instances is short and thick, while in others it is very thick toward the tail and much attenuated near the neck, the head being minute in proportion to the size of the individual. The posterior part of the body and the tail are flattened and compressed vertically, like the tail of a fish, and with it they swim with extreme grace. The fangs and jaws of the sea snakes are generally smaller than those of land-serpents, the venomous teeth having open grooves. That they are venomous is without doubt, as several instances are on record of persons losing their lives, and Fayrer found by actual experiment the dangerous nature of their venom. Belonging to this family are seven genera. *Platurus, Aipysurus, Disteira, Acalyptus, Hydrophis, Enhydrina*, and *Pelamis*, and of these the latter only is known to be found occasionally near the Isthmus of Panama. *Platurus* contains two species; *Hydrophis*, twenty-seven; *Enhydrina*, two; and *Pelamis*, one. The coloration of the sea-snakes varies greatly, one of the most beautiful being *Pelamis bicolor*, the back of which is slaty black, the belly orange. Another very beautiful species is *Hydrophis nigrocincta*, in which the ground color is fawn, the entire body being partly surrounded with lake-brown circles.

In the experiments reported by Fayrer as having been made by Dr. W. P. Stewart, at Pooree, British India, the virulence of the venom of the sea-snakes is abundantly proved.

Fayrer's experiments, which were made upon different sorts of animals, using different kinds of serpent-venom, led him to the following conclusions.

Snake-poison acts with most vigor on the warm-blooded animals; birds succumb very rapidly; a vigorous snake can destroy a fowl in a few seconds. The power of resistance is generally in relation to the size of the animal, though not altogether so; cats, for example, resist the influence of the poison almost as long as dogs three or four times their size. Cold-blooded animals also succumb to the poison, but less rapidly. Fish, non-venomous snakes, mollusca, all die. After death from cobra-poison the blood coagulates, but generally remains fluid after the bite of a viperine serpent.

With regard to treatment of snake-bites, Fayrer tried every reputed antidote and every plan of treatment, but without success, although he believes that ligature, excision, and general treatment seem to afford some chance. Much, however, needs still to be done in the way of experimentation.[3]

It would be foreign to the purpose of this article to give an account of all the venomous serpents of the world, but the names of a few may be added to swell the already formidable list.

In Europe the most dreaded serpent is the *Pelias berus*, common viper; in Australia the *Hoplocephalus curtus*, tiger-snake; in Africa the different species of *Clotho, Megæra*, etc.; in South America the different species of *Craspedocephalus*, the *Jaracacas* and *Fer de lance;* while in Costa Rica particularly is found a genus of venomous serpents known as *Teleuraspis*, which are allied to the *Crotalidæ*, but have no rattles. These snakes are arboreal in habit, and present no less than five color variations, the most beautiful of all being of a golden-yellow color. A peculiarity of the genus is the presence of a series of scales above the eye resembling small horns. It is said that these serpents, which are very venomous, lie at full length along the branches of trees, striking at the faces of passers-by. In Mexico a large *Elaps* and the various *Crotalidæ* are most justly feared.

The illustrations which accompany this article have been drawn with great care by Mr. John Ridgway, of the Bureau of Ethnology, United States National Museum, from certain cuts already shown in the various works on Serpents; in other instances they have been copied from life, and leave nothing to be desired in the way of drawings. The large colored plate of *Crotalus adamanteus* has been drawn from a fine specimen owned by the National Museum, and that of *Heloderma suspectum* is by Mr. A. Zeno Schindler, copied from a living reptile in the same institution. Acknowledgment is also made to the published works of many authors, the most prominent being those by Mitchell and Reichert, Fletcher, Cope, Garman, Fayrer, Halford, and others.

[1] With regard to the very poisonous qualities of the Heloderma saliva recent experiments by the writer would seem to indicate an extremely feeble toxic effect, at least so far as rabbits and fowls are concerned.

[2] It is to be regretted that a repetition of Lacerda's experiments with the permanganate by the writer has not given the results claimed by the distinguished Brazilian.

[3] A series of experiments are now being tried to verify what appears to be decided antidotal effects of Jaborandi to Crotalus venom, the writer having succeeded in saving rabbits which had received fourfold lethal doses of the poison. It has no antidotal effect, however, upon fowls.

Henry Créry Yarrow.

RESECTION OF JOINTS.—In the strictest sense, the terms resection and excision as applied to joints are not synonymous. The former involves the primary idea of the removal of a section of a bone, especially of its shaft; the latter refers more particularly to the removal of the joint as such. As a joint is excised by the resection of the ends of the bones that compose it, the terms in

practice become synonyms, and are so found in standard works. It may be noticed that in French and German works the term resection is commonly employed; in English and American writings excision is more in use. In this article they will be used as practically synonymous. The term exsection is also used in the same sense.

Resections have been divided into *complete* and *partial*, the former meaning operations in which all the component bony surfaces are removed, the latter operations in which the articulating surface of one bone, or of more, in some complex joints, is left. Here again the nomenclature is not always strictly adhered to—as applied to the shoulder or hip for instance,—and writers seem to be not at all agreed as to what constitutes a complete excision of some joints, notably the wrist.

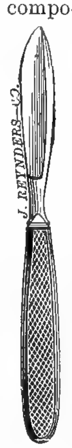

FIG. 3245.

The term osteoplastic is applied to resection in the performance of which a bone or bony prominence (*e.g.*, the trochanter major, the olecranon, or the patella) is divided and the parts temporarily separated, in order to expose the diseased tissues, and subsequently replaced more or less perfectly *in situ*. The same term has been applied to operations analogous to those of plastic surgery in which the sawn surfaces of bones not normally in apposition have been brought together after the removal of the intervening parts; for example, Mikulicz's osteoplastic resection of the tarsus. It is not easy to see why such operations are more osteoplastic than many others in which anchylosis is sought for, ordinary resection of the knee, for instance.

It is unnecessary to enter upon the history of resections. Scattered through surgical literature are allusions to operations, made to meet emergencies, more or less resembling modern resections. But it is little more than a century since Henry Park (1783) first formally proposed the removal of the elbow and knee joints for the cure of disease, and Moreau soon after (1786) made the first complete operation and became the advocate of it as a definite surgical procedure. Nevertheless resections gained footing with such slowness that their real history belongs to the present century, and chiefly to its second half. Excision of the shoulder, by reason of the ease of the operation and the disabling mutilation it promised to prevent, became an accepted operation earlier than the removal of other joints. The labors of Syme, beginning about 1831, made the profession acquainted with the value of elbow-resection, and the authority and teaching of Ferguson in the decade following 1845 fairly put excisions of the hip, knee, and wrist among recognized procedures, however much surgeons differed as to their real value and applicability. Continental surgeons were also engaged in working out the problems of excision, but the influence of the two British surgeons named was especially powerful.

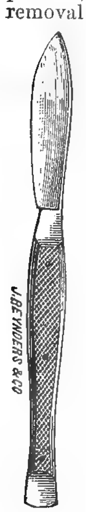

FIG. 3246.

Resection was primarily an attempt to escape the disaster of an amputation. Hodges,[1] in his classical monograph, says: "It is only as a substitute for amputation in traumatic lesions, and in certain organic ones, that the proposition of excising joints has been entertained, excepting in those comparatively few cases in which the operation has been undertaken for the cure of deformities or in disease of the hip-joint where it is the sole operative alternative." It was in the spirit of conservatism that Ferguson in particular urged the resort to excision. To surgeons of the present day, at least in America—excision seems a radical procedure, and they have difficulty in appreciating the condition of affairs existing thirty or forty years ago. To-day, in a case of joint disease, we choose between resection and a highly perfected plan of treatment by joint-rest and expectancy in its best sense. Then the choice was between amputation, on the one hand, and probable death, or, at least, painful and disabling disease of indefinite duration, on the other. Under such circumstances a procedure which gave better chances as to life or function was a boon, and truly conservative, even if hidden under the guise of a somewhat complicated surgical operation.

To establish the true value of resections, it is necessary to determine, first, whether they are really conservative of life as compared with either amputation or expectant

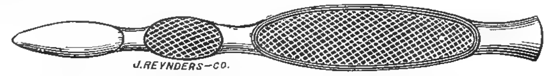

FIG. 3247.—Sands' Periosteotome.

treatment, and, second, whether the limb saved is really a useful member and worth the suffering and the risk. With regard to some joints these points are entirely settled; as to others, there is not yet entire unanimity of opinion. Before the introduction of aseptic surgery, the question of vital conservatism was kept open by the considerable death-rate of excisions, dependent upon prolonged suppuration and its results. Since the change in surgical

FIG. 3248.—Sayre's "Oyster Knife."

methods has reduced the operation-death-rate in civil practice of both amputations and resections to a much lower figure, the question is no longer very important, except as to the results of operative interference of any kind when compared with those of purely conservative treatment. And it should be noted that asepsis has had its influence not on the greater operations alone, but upon the minor substitutes for them, such as incision and

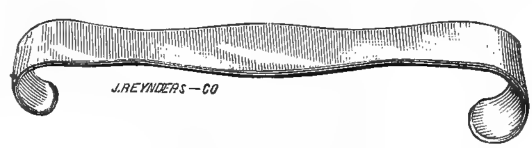

FIG. 3249.—Parker's Retractor.

drainage, as well as upon conservatism pure and simple. The vital prognosis being a matter of less urgent consideration, the functional prognosis has taken a proportionally more prominent place.

There is no doubt that the different estimates at present set upon resection in different countries depend upon the value of its alternatives. In America and in Great Britain, certainly, even before the prevalence of aseptic surgery, resections were almost confined to those classes whose circumstances did not allow them the best kind of conservative treatment. The same, we think, is at least measurably true of other countries, and wherever joint-diseases are very common among the very poor, then operative procedures are not only much more frequently resorted to but are also much more necessary than they would be under more fortunate circumstances.

The *instruments* necessary for resections of joints are essentially the same as those for other operations on bone.

For the division of the soft parts and the denudation of the bone are required knives, periosteotomes, and retractors. The knife should be strong and broad-bladed, the handle roughened to assure firmness of grasp (Fig. 3245). It is sometimes convenient to have the handle terminate in a periosteotome (Fig. 3246), but in operative surgery, as in other mechanical arts, combination-tools are usually annoyances, and perform no one office really well.

FIG. 3250.

Periosteotomes are of very various patterns. The essentials of a good one are that it shall be strong enough for its work, its handle sufficiently large and rough, its edge sharp enough to avoid any contusion of tissues, and

to easily and completely remove the periosteum, while it shall not be so sharp as that of a knife or any instrument intended for cutting the soft parts. Figs. 3247 and 3248 represent two patterns much used in

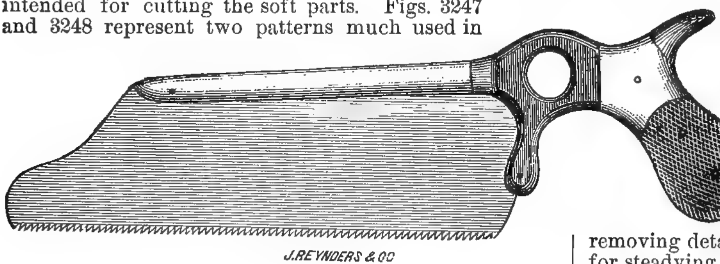

FIG. 3251.

this country. The latter is Sayre's "oyster-knife," and when the edge has just the right degree of sharpness, it is a very efficient instrument. Ollier's periosteotomes resemble dull chisels and flattened gouges.

Retractors may be of thin German silver (Fig. 3249) or

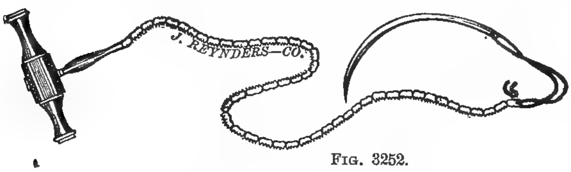

FIG. 3252.

of steel (Fig. 3250), the latter being made of various patterns with sharp or blunt points. Those which give the most certain control of, while doing the least injury to, the parts, are the best.

For the removal of the bony parts various forms of saws and of cutting and holding forceps are required.

FIG. 3253.

The ordinary amputating saw (Fig. 3251) is quite sufficient for most operations on the larger joints. Occasionally other forms of saw are convenient. The chain-saw (Fig. 3252) is useful where it is desired to sever the bone without raising it from its bed in the tissues; as, for instance, the neck of the femur in excision of the hip. In

FIG. 3254.

some situations the small saw with movable back (Fig. 3253) is very convenient, as is the key-hole saw (Fig. 3254). Butcher's saw, with its thin rotating blade, or the similar instrument of Szymanowski (Fig. 3255) is rarely demanded, although useful where cuts of curved or varied directions are to be made. For the division of small

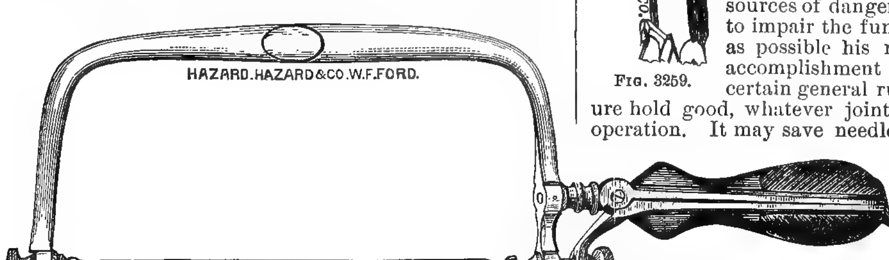

FIG. 3255.

bones the cutting forceps, either straight (Fig. 3256) or bent (Fig. 3257), are often handier than any saw. Cutting forceps of various shapes (Figs. 3258, 3259), and the gnawing, or rongeur, forceps (Fig. 3260) are necessary for the removal of the edges of bone and of diseased parts not otherwise accessible. For this last object gouges, to be used by hand (Fig. 3261) or driven by the mallet (Figs. 3262, 3263, and 3264), are very useful. So, too, are bone-scoops (Figs. 3265 and 3266), and occasionally the chisel (Fig. 3267). For removing detached pieces of bone, and for steadying the parts, the holding forceps (Figs. 3268 and 3269) are needed. For the last-named purpose the "lion-jaw" forceps of Ferguson (Fig. 3270), or that of Farabeuf, are preferable.

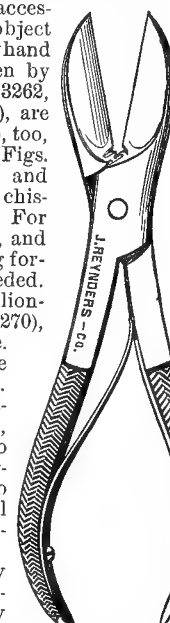

FIG. 3256.

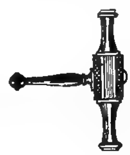
When the bony parts are to be fastened by gut or wire, drills (Fig. 3271) are necessary to the introduction of the suture, and if nails are to be used for the purpose, it is better to make with the drill a preliminary channel to guide them.



The elaborately planned and carefully executed resections of to-day could scarcely have existed previous to the use of anæsthetics; the facility and certainty of their performance have been immensely increased by the Esmarch bandage; and their danger reduced to a minimum by aseptic methods. It is assumed in what follows that, wherever necessary, these adjuvants to success will be employed. Whatever aseptic precautions and dressing are used, they should be those in which the operator has faith and with the details of which he is familiar. In the hospitals of this city (New York), in bone-surgery, the favorite method seems to be the bichloride of mercury for douching; iodoform and iodoform gauze for the wound-application, and iodoform or bichloride gauze for the envelopes. It is convenient and efficient.

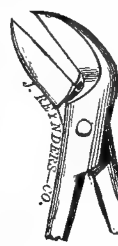


FIG. 3257.

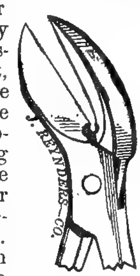

FIG. 3258.

The general law of surgery, to do the least possible damage to the parts consistent with the full accomplishment of the end sought, emphatically applies to joint-resections. To extirpate the disease or to remove the sources of danger is the surgeon's first care, to impair the functions of the part as little as possible his next. To the accomplishment of these ends certain general rules of procedure hold good, whatever joint is the seat of operation. It may save needless repetitions if some of these are considered in this place.

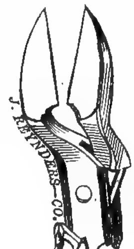

FIG. 3259.

Incisions.—All incisions should be so made as to avoid important vessels and nerves, and wherever possible they should avoid muscles and tendons. The latter requirement can usually be accomplished by using the intermuscular spaces as avenues of approach to the bone. When a muscle must be cut, let the incision

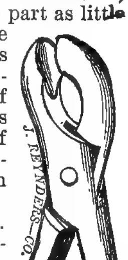

FIG. 3260.

as far as possible follow the direction of the fibres of that muscle, avoiding its nerve. The situation of an incision is often determined by pre-existing wounds or sinuses. Simple incisions are preferable, but should not be adhered to to the embarrassment of the operator ; broken incisions

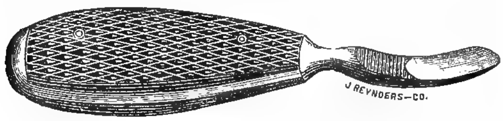

FIG. 3261.

or transverse cuts may sometimes be demanded for convenience. All incisions should be ample, without being excessive ; if the previous rules are observed a long incision is of no harm. Two or more independent incisions are often convenient. It is often possible to make an incision, in a sense exploratory, which will be sufficient for arthrotomy, resection, or amputation, as the condition of the explored parts may demand. Usually the same incision that traverses the overlying parts divides the capsule also. The same rule as regards extent of incision, *i.e.*, ample but not excessive, applies to the capsule as to other soft parts, if it is intended to preserve the mobility of the joint.

FIG. 3262.

Tendons should be preserved in their entirety, and if possible remain undisturbed in their sheaths, and their insertions carefully dissected away from the bone if the latter is to be removed. Or, what in many places is preferable, a small piece of bone may be chipped or pried off attached to the tendon. If by accident or through necessity a tendon is divided, suture of it with catgut is desirable; but the fact that suture of tendons is often successful should not be made a ground for unnecessary injury to them. The occasional surprising restoration of a destroyed or lacerated tendon, and the success following the interposition of a leash of catgut or a piece of animal's tendon in the interval when the divided ends could not be approximated, should encourage the surgeon to every endeavor to preserve the functions of tendons. The management of the *soft parts* during the operation deserves a word. One often sees during an excision the operator or his assistants, intent upon denuding and removing the bone, maltreat the soft parts, forgetful of the processes of repair. The tissues are overstrained to make room which could have been more easily obtained by a more generous incision ; they are torn with sharp retractors or bruised with blunt ones, sometimes lacerated by the violence with which the bone to be sawn is thrust out, and lastly they are teased and nicked by careless sawing. Such errors only need to be pointed out to be corrected.

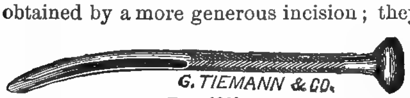

FIG. 3263.

How the *periosteum* shall be dealt with is still an open question among surgeons. Many operators ignore it, or

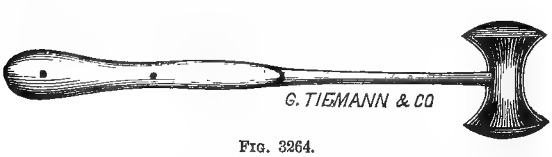

FIG. 3264.

pay little attention to it. The bone having been reached in an operation, it is neatly cleared of the soft tissues by sharp or blunt dissection, with no especial care to save the periosteum. The advocates of the *sub-periosteal method*, on the other hand, insist upon the careful preservation of this membrane. Against the method it has been urged that it is difficult and tedious in execution, and that it has not given better results than the other plans (which Ollier styles the *parosteal*). Further, it has been accused of favoring anchylosis of the excised joint. It is admittedly a slow method, but excisions are rarely undertaken upon patients whose condition demands speed in operation.

FIG. 3265.

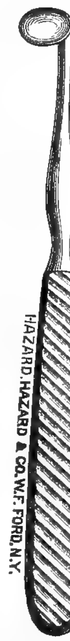

FIG. 3266. — Hebra's Scoop.

Ollier is perhaps the most ardent advocate of the preservation of the periosteum intact, although he has the support of other eminent surgeons, prominent among whom are Langenbeck in Germany, and Sayre in America. The former claims[2] for his method that, by going directly to and through the capsule, and then carefully turning back the periosteum with all its overlying tissues undisturbed, the traumatism is reduced to a minimum ; that the envelope left after the removal of the bones, which he styles the periosteo-capsular sheath, is at once a protection to the soft parts and a support to the bones, retaining the latter in more normal relations during the reparative process ; and that the reparative process is itself much more efficient, and that the functional results are much better than can be obtained by the other method. He further maintains that the method, if time is allowed, is not difficult. Making all allowance for enthusiasm, it would seem that these claims are mainly sound. The chief point, namely, that better functional results are obtained, is the very one that is difficult of proof. Excellent results have been obtained

FIG. 3267.

by both methods. One man's results can with difficulty be compared with another's ; the conditions under which they are obtained may also vary exceedingly. It is, however, fair to say, in estimating the value of the sub-

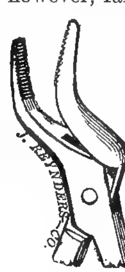

FIG. 3268.

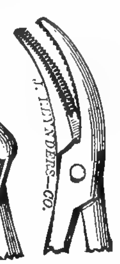

FIG. 3269.

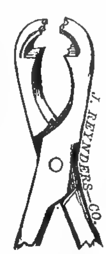

FIG. 3270.

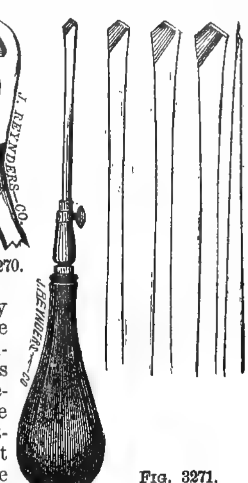

FIG. 3271.

periosteal method, that many operations done under that name are so imperfect as to be worthless as such. The method as employed by Ollier is most careful in details, and the after-care is prolonged and remarkably attentive and painstaking, so that one is left in doubt whether the excellent success in some cases is due to the operative procedure or the after-treatment.

Ollier detaches the periosteum by means of instruments (rugines) much sharper than the periosteal elevators ordinarily in use. They are comparable in this

respect to dull chisels, but are made of various shapes. He maintains that the periosteum should be lifted in its entirety by very careful to-and-fro motions of the tool, and that this can only be accomplished by a rather sharp instrument; a blunt one usually tearing the membrane, bringing away its fibrous part more or less lacerated and shredded, and often leaving behind the bulk of the osteogenetic layer, which alone is valuable for reproduction of bone. To make sure of the removal of this layer, the elevator must be sufficiently sharp and strong to chip the bone when necessary, and whenever he encounters a small prominence or a dimpled surface which is very difficult to enucleate, he slices off a bit of bone with the periosteum, and later on detaches it from within if desirable. As a rule, however, such pieces of bone, if sound and firmly attached, may be well left as aids in the restorative process. A corollary of this last detail is the practice, already alluded to, of leaving a small piéce of bone, if sound, at the point of insertion of a tendon. Every pains is taken to avoid tearing the periosteum or detaching it from its overlying tissues. The same care is exercised in detaching fragments of bone which must be removed in a resection for injury. The whole technique of denudation may be expressed in one phrase: When the elevator has reached the bone, it should never leave it until its work is done. This, in brief, is the sub-periosteal method, and whether it is preferred or not by an operator, it will be readily distinguished from the manœuvres so named in which the periosteum is left behind as a mass of half-connected shreds. In practice it is worth the operator's consideration, to be employed if he thinks he is able in the given case to properly carry it out.

The *bone* to be removed having been denuded by whichever method is selected, it is to be sawn. The slice removed should be, as a rule, as thin as possible. In most joints the end of the bone may be made to protrude through the incision, and the saw is applied outside. If more than one bone is to be sawn, that which is more easily thrust out is sawn first. Great care is to be exercised against unintentional stripping of the soft parts from the bone, although periosteum will generally reunite if kept aseptic. Whatever form of saw is used the soft parts should be perfectly guarded, and metal retractors are usually most convenient and efficient. The saw-cut, especially in places where important vessels or nerves lie near, and more particularly when the bone is not protruded, should not be carried absolutely through the bone, but when it is nearly done the sawing should be slowed, and the fragment be broken off with a pair of forceps or the fingers, or by simply raising it by tilting the blade of the saw. The edge is subsequently trimmed with the cutting forceps or chisel. If the chain-saw be used this last precaution is not so necessary, as the cut comes toward the operator and away from the parts endangered. The chain-saw can easily be introduced by tying the free end to an eyed probe, or to a curved needle, which is then carried beneath the bone. Before beginning to saw, the chain should be carefully straightened, as any kink pretty certainly causes it to break. A common error in its use is the bringing of the two handles too near together, making too short a turn around the bone, which also favors breaking. The hands should be widely separated, so as to make but a slight angle in the chain as it cuts the bone. It is drawn to and fro very steadily, the chain being always kept taut between the hands. While convenient in certain cases, it is a far less perfect tool than the common amputating saw. A very convenient instrument for sawing bone *in situ* is the "Exsector" (Fig. 3272), devised by Gowan, and modified in this country by Wyeth. It combines a powerful grasping forceps with a saw. The latter is at the end of an instrument shaped somewhat like an ordinary screw-driver; it passes through a guide, which again turns on a pivot. The bone-end to be sawed is tightly grasped by the forceps, the saw pushed through the guide until it touches the bone, the handle is moved forward and backward, and the saw-end rapidly cuts the bone cleanly and safely.

In the removal of some joints various devices of coaptation, by sawing the bones into particular shapes—notches, mortise and tenon, etc.—have been employed. They have their advantages, but should not be employed at the expense of sound tissue, and the operator must be prepared to make his decision after he has seen the parts to be removed.

The bones having been sawed, the surfaces are critically examined by eye and touch, to ascertain if the entire amount necessary has been removed. If the resection has been made for disease, this examination reveals any point of bone actually or probably diseased. If found, they are removed by the gouge, chisel, or scoop. If very extensive, a second slice may need to be removed by the saw. All suspected bone, at least in cases of tubercular disease, should be extirpated. It should, however, be borne in mind that the artificial anæmia produced by the elastic bandage may give to the bony surface such a pale or grayish color as to lead to an unduly wide condemnation of bone; in case of real doubt, the elastic band may be loosened. The edges of the bone being made smooth, if, as in the knee, anchylosis is to be sought, the sawed surfaces are approximated, in order to ascertain if the resulting limb will have the right position. If motion is expected, a similar but less close adjustment is generally made, to judge of the probable suitability of the new articulation. This latter precaution is chiefly of value when the excision is for the relief of anchylosis. Any errors in the adjustment of the sawed surfaces are then corrected by the saw or cutting instrument.

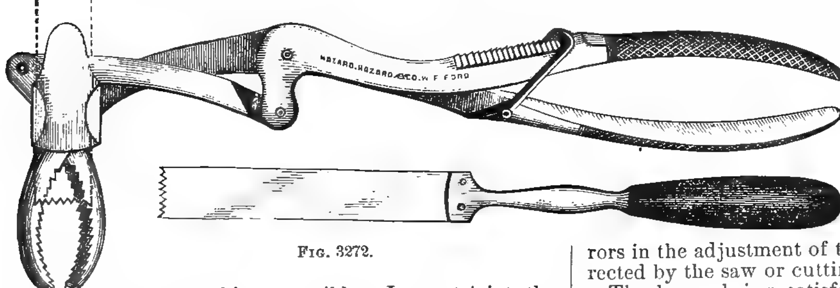

Fig. 3272.

The bones being satisfactorily arranged, the *synovial membrane* is next attended to. All fungous parts are cut away with scissors or scraped with the sharp scoop. As these fungosities are believed to be usually tubercular in their nature, the extirpation cannot be too thorough. If anchylosis is expected, the whole membrane may as well be dissected away, and in any case of doubt it is safer to err on the side of thoroughness. The actual cautery and some cauterants have been used, but their proper place, as applied to synovial membrane, seems to be where the spoon or scissors cannot be employed. As to how far this extirpation should be pushed beyond the synovial membrane—that is to say, to what extent the capsule and ligaments should be sacrificed—authorities are not agreed. Although assent has been given above to the doctrine of thorough extirpation, it cannot be denied that it has sometimes been applied too rigorously. In each step complete examination should precede destruction.

Extirpation completed, the *vessels* are to be looked after. Some may have been recognized as exposed or cut, and twisted or tied at the time. The removal of the Esmarch bandage will reveal any other bleeding points, which will be secured in the usual way, and a hot antiseptic solution will check the oozing. Some operators, when sure that no considerable vessel has been hurt, do not remove (from some joints, at least) the Esmarch bandage until the wound is entirely dressed and the limb has

been placed upon its temporary splint. By so doing the pressure diminishes the amount of oozing, and the demand for drainage is less.

But in all cases the *drainage* must be thorough and complete. The position of the drains should be in such places as to drain the wound whatever position the patient may occupy. Bone-drains are much used for the purpose. It often occurs that after a few days no tubes are needed, and they may be withdrawn and the joint enveloped in its permanent antiseptic dressing. Ollier, whose technique is characterized by the most anxious carefulness, prefers to make his drainage-incisions at the start, because the relations of parts are then undisturbed, and less risk of damage is incurred by making them from without inward thus early. Few operators, however, can tell in advance the extent of the operative cavity that will require drainage with sufficient accuracy to thus early place the drains, and the usual method of waiting till they are needed is, on the whole, probably preferable.

When anchylosis is sought it is more certainly gained, both as to solidity and as to position, if the parts are securely fastened together. As will be shown later, such *fixation* is not absolutely necessary, but is of great convenience. Ordinary suturing materials—silk, catgut, and the like—will serve in case of need; but usually pretty stout wires, either iron, silver, copper, or silvered copper, are employed. To introduce them, bone-drills are necessary. In using the drill it should be carefully passed through one of the bones from its outer surface, beginning an inch (more or less according to the size of the bone) from the sawed surface, in a diagonal direction, so that it perforates the sawed surface sufficiently far from the edge to insure a strong hold. The bones are then placed together in the desired position, so that the point of the drill may show where the other bone must be drilled, and a hole carried from this point out to the surface of the second bone. In this way channels for two or more sutures in the best positions for insuring firmness are made, and the wire, carefully straightened, is carried through. When all are in place the surfaces of the bones are approximated and the wires tightened, and when the former are in the desired position the wires are made as tight as possible and twisted. To avoid difficulty in removal, it is usual to adopt a fixed way of twisting, say from left to right, and to make a certain number of twists, of which a memorandum is kept. This renders the untwisting at the time of removal certain, and no doubt remains in the mind of the operator as to whether he has completely untwisted the wire, or has overdone it and begun to retwist it in the opposite direction. It is now well known, however, that an aseptic wire may be safely left in the tissues, and the precautions above described to get rid of an irritant which tended to prolong the suppuration always attending a resection are now no longer really necessary.

A still further improvement is the use of nails instead of wire to fasten the bones together. They are easier to introduce, and much easier to remove. Nails for the purpose are made by the instrument-makers, and are sometimes plated, an unnecessary refinement. It is an advantage that they should be of steel rather than of iron, as strength and rigidity can be thus had without undue thickness. They may be of round or square wire, and should be very smooth, in order that they may be the more readily made aseptic. They should be of good length, in order that after the necessary penetration for security is had some part of the nail may project through the soft parts to render its removal easy. Preparatory channels are made with the bone-drills, starting from various points on the outer surface of one bone and carried straight on into the other, the two being held in juxtaposition meanwhile. The directions of the nails must not be parallel, in order to prevent the bones drawing apart. This may be assured by introducing the nails diagonally from two or three different aspects of the bone. The nails, which should be very slightly thicker than the drills, are driven into the prepared holes.

Still more convenient are the drills (Fig. 3273) of Dr. Wyeth. They are set in a movable handle. The long, slender shaft is readily introduced, and the handle is then detached, and the drill serves as a nail until the time for its removal arrives.

Howard Marsh[3] recommends the use of bone-pins—bone knitting needles will serve very well—for fastening the bones. It is not necessary to withdraw them if it is not perfectly convenient to do so.

Whatever method of fixation is employed, great pains should be taken to exclude everything from between the sawed surfaces of the bone, whether it be folds of tissue, drainage-tube, or anything else.

In closing the operation-wound, if there be fair reason to expect prompt union, it should be neatly closed except at the drainage-apertures. If, after the extirpation of the disease, the capsule of the joint has been left behind its cut edges may be sewed together with catgut before the outer parts are sutured. If anchylosisand consolidation are lookedfor, the superabundant tissues may be brought together both by deep and superficial continuous sutures.

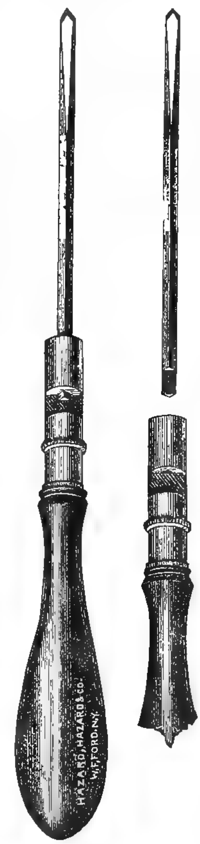

Fig. 3273.

Indications.—The indications for resection vary somewhat with different joints, but the general rules are the same for all. For chronic fungous disease excision is indicated when expectant treatment has failed, and no less extensive operation is sufficient to arrest the progress of the disease. Just what condition of the joint justifies the opinion that expectancy has failed will vary according to circumstances presently to be referred to. But excision should not be considered as a substitute for, or alternative of, expectation ; it may be its sequel in case of failure. This cannot be too strongly insisted on, in view of the tendency of some surgeons to look upon excision as a short road to the cure of chronic joint disease. Nor should the opposite error be adopted, of believing that because among the well-to-do excision is of the greatest rarity such operations are uncalled for elsewhere. In America an intelligent and efficient expectant treatment of joint diseases by rest, fixation, and traction has been so long established that it may seem idle to discuss this point. Not only among the prosperous or comfortable classes is the expectant plan successful, but the result of work done among the poor by the special dispensaries and at clinics is on the whole very satisfactory. But there is, and probably always will be, a certain proportion of cases that cannot or do not get good expectant treatment, or in which it fails. In considering the indication in these cases it is quite irrelevant to urge the success that has attended expectancy in more fortunate ones; they must be considered by themselves. If there is necrosis with a sequestrum of such size as will not readily pass through a fistula, some operative procedure is imperative. But the existence of neither suppuration nor caries, nor the lapse of any particular amount of time, is of itself an indication for resection. A safe rule is this : If, in spite of the best hygiene and the best care that the patient can command, either at home or in charitable institutions, suppuration exists and *persists ;* if there is with it fever, or if the condition of the patient is deteriorating, operative interference of some kind is indicated—either resection or some of its substitutes. It is evident that the decision will be often determined really by what are called the extra-medical indications—that is to say, by the social status of the patient, by what com-

forts he can command during prolonged expectant treatment, and by the necessity of the use of the affected joint in earning his living.

As against amputation, excision is always to be preferred in civil practice, unless the extent of disease threatens that the saved limb will be more useless than a stump would be. As against arthrotomy, with the removal of diseased tissue in an informal manner, no certain rule can be given. Such operations frequently succeed, but relapses demanding excision are also not rare. If the bones be diseased, the removal of the affected parts piecemeal may make a practical resection under another name. The indications for such procedures are very different for different joints, and will be alluded to under those headings. The general rule, however, is that in children, and especially young children, informal resections are to be preferred, the shoulder and hip, perhaps, making exceptions to this rule.

There have been for some time, particularly among German surgeons, many advocates of early excisions. The failures after operations have been considered as largely influenced by delay in operating, and in recent years theories as to the tubercular nature of joint diseases and the success attending aseptic surgery have tended in the same direction. It is held that since fungous joint disease is tuberculous, extirpation is the readiest if not the only certain way of curing it, and at the same time is a safeguard against the generalization of tuberculosis. So that by a single operation the danger to life is diminished and time saved. The tuberculous nature of most fungous joint disease may be conceded, but it is impossible to set inferences regarding the results of tubercular disease against general clinical experience. The latter shows us that, taking one country with another, such joint diseases in the majority of cases do recover without serious operative interference. The vital indication for early excisions therefore fails, unless it can be shown that a larger proportion of cases are cured with excision than without. This has not been shown. Further, it has not been shown that excision, even with antiseptic precautions, has diminished the tendency to other tuberculous diseases. The most considerable contribution to this question is König's.[4] Of 117 excisions of all sorts, made during three and one-half years, 25 died ; 18 from tuberculosis, while 9 others still alive were hopelessly tuberculous. Other less extended lists give similar results. The tubercular infection of the operation-wound is common, although such affections very often yield to secondary extirpation. The operative procedure not rarely explodes some remote tubercular trouble—meningitis, pleurisy, etc.—following within a few days of operation. In respect to tubercular infection of remote parts, the results gained by aseptic surgery have been little, if any, better than were had before.

The existence of pulmonary tuberculosis is generally held to be a contraindication of any resection, but the rule is not absolute. When the pulmonary lesion seems to be secondary to the joint trouble, quiescence of the former occasionally follows the removal of the latter. If the pulmonary tuberculosis is primary, resection is only mischievous.

In acute suppurative arthritis, the success of antiseptic arthrotomy has been such as to make it preferable to excision of the joint. It should, at least, be tried in ordinary cases before resorting to the latter operation.

The results of resection for gunshot fractures of joints are so different in military surgery from those done in civil practice, and vary so much with different joints, that the indications must be given under each head. The same will be done for resections for deformity.

Aseptic methods have diminished the objections, formerly valid, to partial resections, and in gunshot resections the informal, or untypical, methods are usually preferable.

Trophic disturbances of the limb, as distinguished from simple atrophy of inactivity, seem to be more common after gunshot resections than after operations for pathological causes.

Resection of the Shoulder-joint has been long established as a standard operation of surgery. Extraction of fragments of the head of the humerus after gunshot injury had been done for some years, when Charles White,[5] of Manchester, England, in 1768, removed, as he believed, the head and part of the shaft for disease. James Bent, of Newcastle, England, published, in 1774[6] an account of a true excision of the head of the humerus for disease. He pointed out the fact that Mr. White had not removed the head, and that the bone removed at the first operation ended at the epiphyseal line. White's report and plate seem to justify this criticism, although his claim was made in good faith. Bent (1771) or Lentin (1771), probably, should have the credit of priority. The first complete excision of the shoulder is attributed to the elder Moreau (1786). Larrey seems to have first introduced excision of the shoulder into military surgery in the Egyptian campaign (1798). Thereafter the operation gained in professional esteem, and on the Continent its value may be said to have been established by the experience of the Schleswig-Holstein campaign of 1848, the Crimean war (1855), and in this country by our own war (1861–65).

Owing to the relative infrequency of disease of the shoulder,* as compared with other joints, operations for disease are far less numerous than for gunshot wounds. Culbertson collected 855 cases of excision for gunshot wounds, 12 for other injuries, and 116 for disease.

The mortality of resection for gunshot injury of the shoulder-joint is not relatively high, being, according to Culbertson, for all operations, complete and partial, 31.44 per cent., most of the observations belonging to the pre-aseptic period. Operations for disease give a still smaller mortality. The same author gives (omitting cases of malignant disease) 101 cases, with 16 deaths, or 15.84 per cent. Otis[7] gives the comparative mortality for gunshot injuries of the shoulder thus: "Of 2,369 determined cases, 577 were treated by expectancy, with a mortality of 25.1 per cent.; 951 by excision, with a mortality of 36.6 per cent.; 841 by amputation, with a mortality of 29.1 per cent.—in all, 738 cases terminating fatally, or 31.1 per cent." The statistics of more recent wars, as far as attainable, seem to show no great variation from the above.

In civil practice, under modern methods, resection undoubtedly gives a smaller death-rate, but no extended statistics can be given.

Results.—While it appears that the immediate mortality of resection of the shoulder-joint is somewhat greater than that of amputation for gunshot injury, the incomparably better result—the saving of an arm—in case of success, has made resection of the shoulder one of the triumphs of military surgery. To escape amputation is to save a hand and elbow, even if the functions of the shoulder-joint are seriously impaired. Gurlt[8] gives the functional results of resections made in German wars between 1848 and 1871. He divides them into five classes: I., "very good," those which are perfect or as perfect as is possible; II., "good" results, not perfect, but members very useful; III., "middling," members of some use, but perhaps needing artificial support; IV., "bad," members not useful; V., "very bad," not only not useful, but burdensome. Of 213 cases of shoulder resection, the percentage of results is: I., 1.87; II., 42.25; III., 47.88; IV., 7.98; V., 0; or, roughly, good, 44 per cent.; middling, 48 per cent.; bad, 8 per cent. Remarkably useful shoulders are sometimes obtained, as witness cases figured by Langenbeck,[9] or the case reported by MacCormac[10] of a Chasseur d'Afrique injured at Sedan from whom, twelve days later, he removed the shoulder and elbow joints of the right arm. The strength and utility of the arm were remarkable (see Fig. 3274, showing limb passive and active).

A common imperfection of result, both at the shoulder and elbow, is preternatural mobility, or "flail-joint." In spite of this want of firmness at the shoulder, the arm is often very useful. Gurlt found, in the cases before al-

* The writer has added the lists of several hospitals, American and foreign. Of 1,368 cases of joint diseases, 22 only were of the shoulder—less than two per cent. In one hospital, for one year, there were 10 out of 320 cases; in another, only 5 out of 540—that is, about three per cent. of all cases for the highest, one per cent for the lowest.

luded to: Closely knit joints, 45.07 per cent.; flail-joints, 35.68 per cent.; anchylosed joints, 9.86 per cent.; unknown but not anchylosed, 9.39 per cent. There is little doubt that the careful sub-periosteal resections urged by Langenbeck and Ollier give much better results as to flail-joint, as well as in other respects, than the older methods. Not only is the muscular structure less damaged, but the reproduced bone gives a better *point d'appui*, the loss of which has been considered a main reason for the difficulty in raising the arm above the horizontal.

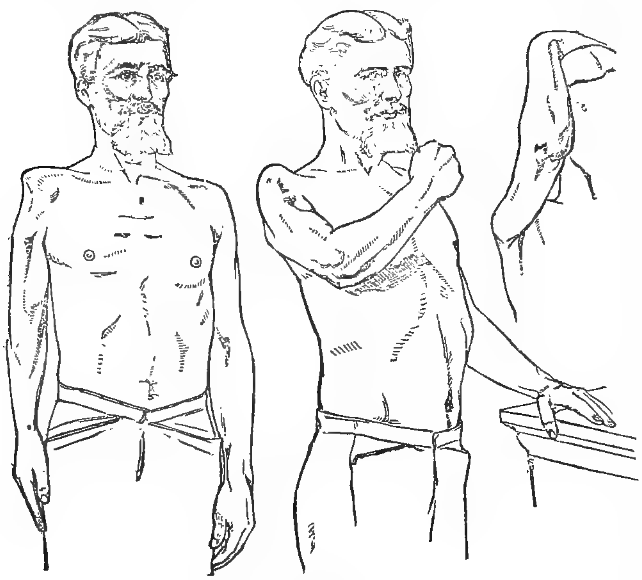

Fig. 3274.

Indications.—The experience of the war of the Rebellion and of the German wars between 1848 and 1871, as analyzed by Otis [11] and Von Langenbeck, [12] goes far to settle the indications in gunshot injury of the shoulder. If the injury is slight, expectant treatment is justifiable, even if a secondary resection becomes subsequently necessary. In cases in which a part only of the head has been broken off by the shot, partial excisions, *i.e.*, removal of the injured part only, have succeeded. If extensive (comminuted) fracture of the head exists, or the ball is impacted, the main vessels and nerves being sound, primary resection is indicated. "Concomitant fractures of the acromial end of the clavicle, or of the neck, or processes of the scapula, or of the upper third of the humerus, do not necessarily contraindicate excisions at the shoulder" (Otis). Nor, according to Langenbeck, does shattering of the shoulder-joint with laceration of the soft parts necessarily indicate exarticulation, but rather a secondary resection. "Intermediary resections should seldom or never be practised" (Otis). Injury of the axillary nerves and vessels complicating shot-wound of the shoulder usually calls for exarticulation.

Resection has also been held as indicated in compound dislocation, in compound fracture with protrusion of fragments, and in some forms of laceration of joint-structure. The success of aseptic dressings, however, has made these indications less distinct than formerly, and if reduction can be accomplished and asepsis insured, the surgeon may decide between resection, or the aseptic expectant treatment and subsequent osteotomy in case of too rigid anchylosis resulting.

For fungous arthritis resection is demanded when expectant treatment has not succeeded and the strength of the patient is failing. There is then a vital indication for interference. If on the joint being opened the bony parts are found to be not involved to any extent, gouging and scraping may suffice, but the relative advantages of informal operations over the formal are not so great at the shoulder as in some other articulations. The great success of resection justifies its use in any case in which there exists much risk to life from exhaustion or from the sequels or complications of prolonged suppuration. Functionally, the results of resection are not so much superior to those of cure by anchylosis, more or less complete, as might be at first thought. Owing to the mobility of the scapula, a great deal of motion is permitted to the arm, even if no motion takes place at the shoulder proper, and in some excellent results with motion after resection the portion of the mobility furnished by the sliding scapula has been found to far exceed that in the joint itself. This is, however, not always true, but the facts stated have led some surgeons to advocate the securing of cure by anchylosis if practicable, rather than by resection, and to make subsequent osteotomy, if necessary, as before mentioned. This supplementary mobility being greatest in the very young, the age of the patient may determine the surgeon's choice of procedure.

Methods.—Very many forms of incision have been employed for the removal of the head of the humerus, such as the **V**, the **U**, the **T**, the **˥**, single or double and inverted, and others, but practically, when the surgeon has a choice, all have now given place to the anterior longitudinal incision. The injury, particularly if a gunshot wound, for which the resection is performed, may have determined site of the operative wound, or if the muscular the cap of the shoulder is already badly torn, little additional damage will be done by making use of the same opening for the removal of the bone. But in the operation for disease, or whenever the surgeon may choose, the straight anterior cut is to be preferred because of the less injury it inflicts upon the muscles. The two varieties of this incision are Langenbeck's and Ollier's. Langenbeck's original procedure has been modified by him so as to become a sub-periosteal method. The first is as follows: [13] The patient lies upon his back, with the shoulder raised upon a pillow; the arm is held so that the external condyle of the humerus is directed forward. An incision, beginning at the anterior border of the acromion, quite close to its articulation with the clavicle, and running for six to ten centimetres (2½ to 4 inches) vertically downward, divides the deltoid muscle and reaches the capsule of the joint and the periosteum (Fig. 3275). The muscle is retracted on both sides of the incision; the tendon of the long head of the biceps is seen lying within its sheath. An incision along the outer side of the tendon opens its sheath; the knife is directed upward with the back of the blade in the bicipital groove, and divides the whole length of the sheath, together with the capsular ligament up to the acromion.

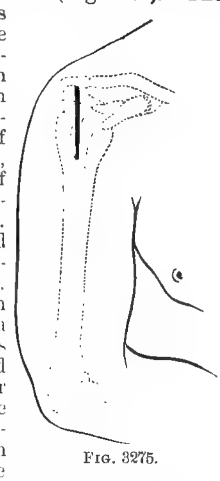

Fig. 3275.

The tendon of the biceps is lifted out of its groove and drawn outward with the blunt retractor. While the assistant rotates the arm outward, a curved incision, with a strong knife placed at right angles upon the bone, is carried around from the opening in the joint over the lesser tuberosity, dividing the capsular ligament and subscapularis muscle. The arm being again rotated inward, the tendon of the biceps is also drawn inward over the head of the bone. The knife is again carried around in a larger circle over the greater tuberosity and divides the capsule together with the insertions of the supra-spinatus, infra-spinatus, and teres minor. The head of the humerus is forced out of the wound by pressure from below, seized with the forceps, and after the posterior insertion of the capsule has been divided, removed with the keyhole saw. When the head of the humerus is separated from the diaphysis by the bullet, it must be drawn forward, and fixed by a sharp

bone-hook or bullet-screw. If shattered in many pieces, the fragments are removed separately.

Better results, however, are obtained by the use of the sub-periosteal method. The incision, described in the paragraph but one above, having been made, the periosteum is divided with the bone-knife along the inner border of the bicipital groove, and carefully raised with a narrow elevator from the lesser tuberosity. The tendon of the subscapularis is pulled from the bone with the knife and toothed forceps, without separating the fibrous capsular ligament from the liberated periosteum. During this part of the operation the humerus must be slowly rotated outward, and as it becomes more and more liberated, the knife is frequently changed for the elevator. The arm is rotated inward again, the tendon of the biceps lifted from its groove, and slipped over the head of the bone to its inner side. The periosteum on the outer surface of the neck of the humerus, together with the insertion of the supra-spinatus, infra-spinatus, and teres minor into the great tuberosity, are detached in the same manner as before. This preservation of the periosteum is rather difficult in primary excisions for gun-shot injury, because it is usually normally so thin. The head of the humerus is forced out of the wound and sawn off as in the preceding operation. If only the head above the tuberosities is to be excised (which always gives the best result), there can be no question about detaching the periosteum. Beginning from the interior of the joint the muscular attachments are peeled off from the bone as far as is requisite; care is taken that they are not divided transversely, but that their connection with the bone below is preserved. The head must be removed *in situ* with the keyhole, or chain-saw.

Ollier's [14] method differs somewhat from the preceding, and is as follows: The elbow is abducted nearly to a right angle. The incision is made in the interspace between the pectoralis major and the deltoid, or, if this is not easily recognized, from the point of the coracoid process downward and outward in the direction of the fibres of the deltoid. If the border of the deltoid is recognized the incision should slightly encroach upon the muscle in order to avoid the cephalic vein, which last should be left in the inner lip of the wound. The edges being retracted, the head of the humerus is exposed. The capsule is opened by carrying the incision through it outside of and parallel to the tendon of the biceps (long head). The same incision divides the periosteum as far as required. The outer lip of the wound is raised, the periosteum detached by the sharp periosteotome, the bone being inverted by an assistant. All the attached muscles are raised with the periosteum. The arm is then everted and the bone denuded on the inner side. The head of the bone is then luxated, the posterior part of the capsule detached, the neck denuded. The bone is then sawn with any saw preferred.

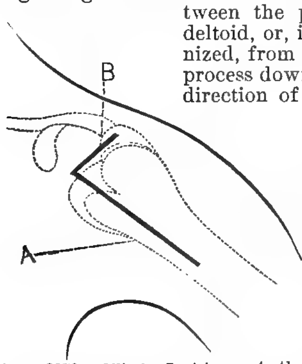

Fig. 3276.—Ollier's Incision. *A*, the principal incision; *B*, cross incision if necessary for excision of glenoid cavity, etc.

After-treatment.—No splint is really necessary, the aseptic dressing and shoulder spica being sufficient, while the patient is recumbent. The arm should preferably be abducted at first. If it is found desirable that the patient sit or walk, an axillary cushion and sling, or a plaster bandage will be needed for support. Passive motion must be begun early, as soon as the tissues are well consolidated. Persistent care is essential to the best results.

Resection of the Elbow appears to have been one of the earliest of resections, Wainman having, in 1759, resected the lower end of the humerus for a compound luxation of the elbow, and Filkin having excised this joint for disease three years later. But like other excisions it came slowly into general use. Symes' advocacy of the operation had considerable influence among British and American surgeons, and during the following twenty or thirty years it became established in civil practice; while the wars on both continents from 1848 to 1871 gave large opportunities for testing its merits in military surgery.

Results.—Culbertson gives the following percentages of mortality as the result of his table of cases, mainly from the pre-antiseptic period. For gunshot wounds, "partial" excision, 27.02 per cent.; for "complete," 25.30 per cent. For injury, "partial," 7.40 per cent.; "complete," 21.05 per cent. For disease, "partial," 11.11 per cent.; "complete," 9.94 per cent. In this classification only those resections are considered "complete" in which the lower end of the humerus with the upper ends of the radius and ulna, or of the ulna alone, are removed. Removal of head of the radius with the lower end of the humerus is considered a "partial" operation. These figures as regards resections for gunshot injuries are not much different from those of Gurlt, who gives 27.41 per cent. for all operations by German operators in the war of 1870–71, and 26.64 per cent. for the German wars 1848–71. These percentages with that of our own war (23.70) give a total percentage of mortality for all operations of 25.10; the complete operations giving 25.40 per cent.; partial, 23.07 per cent.; operations of unknown extent, 30.60 per cent. Partial operations were much more frequent during our own war than in the German wars. Otis's tables show that the time of operation in our war very much modified the death-rate; it being for determined cases only, primary operations, 21.3 per cent.; intermediary, 35.2 per cent.; secondary, 9.2 per cent.; time unknown, 8.3 per cent. The total mortality of elbow resection in our war, 23.7 per cent., may be compared with that of amputation in the upper arm, which was 23.6 per cent.* The comparatively low death-rate of operations for disease (10.4 per cent.) for all of Culbertson's cases will be noted, but no extended statistics are at hand to show how great the purely operative mortality is, and how much is to be attributed to the progress of the disease. That under favorable circumstances the mortality is very slight is shown by the fact that Culbertson gives no deaths for excision for deformity, and Salzman (quoted by Ollier) puts the mortality of resection for anchylosis at 1.47 per cent.† Age affects mortality, the death-rate being for disease least between ten and twenty years of age; for gunshot injury least between twenty and twenty-five years of age. The relative fewness of soldiers under twenty, and the inability of the immature to bear the hardship of campaigning, account probably for the greater percentage of mortality between fifteen and twenty.

The functional results of resection of the elbow are, in civil practice, in general, very good. The joint is not infrequently nearly perfect in function, and strong enough for ordinary occupations, and sometimes even for laborious work. The precise degree of success cannot certainly be made out from statistics, as in some groups the ultimate result is wanting in a large proportion of cases (*e.g.*, Culbertson, excision for gunshot injury, 62.86 per cent., "not stated"). Culbertson gives 40 cases of recovery from "partial" resections for disease, with 6 "perfect" and 32 "useful" joints, together 80 per cent. Of 290 recovered "complete" resections, 32 were "perfect," 196 "useful," together 78.6 per cent. The pension inspections have given opportunities for critically observing the remote results of resected joints, and Gurlt gives the following for the resections of the elbows made in the German wars from 1848 to 1871, the classification being the same as for shoulder resections given above: Very good, 5.63 per cent.; good, 23.66 per cent.; mid-

* For the lower third of the arm only, 35.2 per cent.

† Ollier (Revue de Chirurgie, 1882, p. 717) says that in a series of fifty cases since 1876 he has had no death attributable to the operation. Previous to 1876 he had twelve deaths in sixty-three operations. The improvement he attributes to asepsis and earlier operations, which render the operation less extensive in patients less exhausted.

dling, 53.24 per cent.; bad, 14.37 per cent.; very bad, 3.09 per cent.

The restoration of the resected parts is often quite extensive, and many autopsies have been made upon such restored joints. Nepveu [15] has collected some twenty-one observations. The commonest peculiarities are forked or malleoli-like developments of the condyles, or instead an olecranon-like prolongation of the humerus. The olecranon is sometimes absent, and its place supplied by a radial or humeral prolongation. The coronoid process is often absent. There is usually some restoration of cartilage. The general form of the new joint is similar to that of the ankle.

Indications.—Resection was formerly held to be indicated whenever in a gunshot wound of the elbow the bones were found to be implicated, while the extent of the injury did not make amputation the preferable operation. More recent experience has made the indication less absolute. Otis [16] expresses the result of the latest extensive military experience when he says: "1. That in shot wounds in young healthy subjects, attended with slight injury of the articular extremities of the bones of the elbow, such as fractures of the olecranon, of the outer condyle, or of the trochlea, without much splintering and without lesion of important vessels and nerves, it is justifiable, in many instances, to attempt an expectant conservative treatment, keeping the injured extremity in entire rest, after removing any detached fragments or foreign bodies, in a semi-prone and very slightly flexed position, employing ice or other cold applications." If inflammation occurs it should be met by drainage and appropriate treatment, and if necessary secondary operations resorted to. "Unless all the favorable conditions mentioned are present at the outset, it would be safer to resort to primary excision or amputation. 2. In grave shot comminutions with lesion of the principal vessels or nerves, amputation should be practised immediately after the reception of the injury. 3. In severe shot fracture without extensive lesions of the soft parts, the joint should be freely exposed by a longitudinal posterior incision, and the full extent of the fracture ascertained. Unless there is extraordinary fissuring, the injured joint ends should then be sawn off as close to the limits of the injury as possible, save that the bones of the forearm should be shortened to the same level. If the splintering extends very far, or if there is reason to believe that the humeral vessels are injured though not wounded, the incisions should be so modified as to convert the operation into an amputation." If by reason of the success of aseptic dressing the above needs modification, it is only in enlarging somewhat the range of cases amenable to expectant treatment and in diminishing the weight that splintering of bones gives to the indication for amputation.

For disease, after infancy has passed, resection is indicated, as in other joints, whenever it is clear that expectancy has failed or will fail; that is to say, whenever the best treatment and hygiene at the command of the patient has not arrested the advance of the disease, or if after prolonged trial no material improvement has occurred. While not absolutely indicated, resection is also worth considering if, although the case is progressing toward cure by anchylosis, the position in which anchylosis must occur will be a disadvantageous one. Anchylosis at the shoulder is palliated by the mobility of the scapula, at the wrist, the tendons being free, by the mobility of the fingers. At the elbow there is no considerable compensation, and the very complex function of this joint makes anchylosis of it often very embarrassing.

For anchylosis actually existing resection seems to be indicated in the young, that is to say, until the age of twenty or twenty-five years, if the position of the joint is decidedly disabling, as, for instance, that of total extension. The indication is increased in strength by the existence of double anchylosis, especially if symmetrical as to position. If the two joints be flexed at different angles, the sufferer may be able to perform many of his duties; but a symmetrical anchylosis usually materially disables him.* In such a case excision might be indicated even if anchylosis in a better position were the only gain. It should be borne in mind that the lower epiphysis of the humerus and the upper epiphyses of the radius and ulna contribute but a small part of the growth of the arm. Ollier thinks about one-tenth of the total growth, so that resection of the elbow in early life does not greatly shorten the limb. In adult life excision for anchylosis gives less satisfactory results. In every case of anchylosis the condition of the muscles as to vitality and possible redevelopment must be considered before resection is determined upon.

For gunshot wounds total resections have been considered indicated. The experience of our own war and, to a certain extent, that of the Franco-German war has shown, however, that under favorable circumstances partial operations may do well. For disease the rule is the same, although partial resections of late years are found to be less disadvantageous than formerly supposed. In childhood informal resections have grown in favor; many German operators urging them in place of typical resections.

For anchylosis the resection must be total. But as the age increases the power of reproducing bone diminishes, and consequently in adult life the bone cannot be so freely removed as in youth without endangering flail-joint.

Methods.—Many forms of incision have been employed, and as far as can be judged from Culbertson's statistics no marked difference in results follows the different incisions. The incision of Liston (⊢, the longitudinal part being along the inner border of the olecranon and the transverse portion across the back of that process to the lower border of the external condyle) has been much employed, but at present single longitudinal incisions are deemed to be in ordinary cases sufficient. If the form of the existing wound or other reasons make it preferable some other incision should be employed. Of the longitudinal incisions Langenbeck's subperiosteal method is probably the most frequently resorted to. It is as follows: [17] An incision eight or ten centimetres in length is made over the extensor surface of the joint, somewhat to the inner side of the middle of the olecranon, the tip of the olecranon being above the centre of the cut. (See Fig. 3277 in which the incision is placed too high.) This cut goes down to the bone throughout its course. The periosteum is first elevated toward the inner side and the inner half of the tenden of the triceps, together with the periosteum, is divided by short parallel longitudinal incisions directed against the bone. The soft parts, covering the internal condyle and inclosing the ulnar nerve, are drawn by the left thumb-nail toward the tip of the epicondyle, and liberated by curved incisions close together and against the bone until the epicondyle is completely exposed. The last incisions are carried around this prominence and separate the origins of the flexor muscles as well as the internal lateral ligament from the humerus, without however disturbing their connection with the periosteum. The tissues are replaced and the outer part of the tendon of the triceps and the anconeus are detached with the periosteum, and in the same careful way described the capsule is raised and the external condyle reached and cleared, the external lateral ligament and the extensor muscles being raised with the periosteum of the humerus. Both condyles being free, the joint is

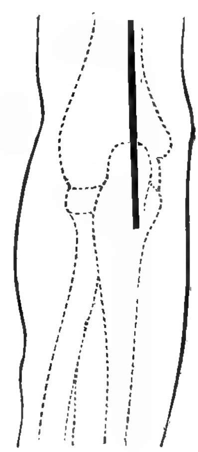

FIG. 3277.—Langenbeck's Incision.

* Double anchylosis appears to be most common as a sequel to small-pox. Such cases are frequently referred to in continental articles, and the writer has met with two cases from this cause.

forcibly flexed, the articular surfaces forced out of the wound. The humerus is steadied with the forceps and the articular surface sawn off. The ulna and the radius are then sawn. If it be necessary to go below the coronoid process, the upper fibres of the brachialis anticus must be divided, without destroying the connection of the tendon with the periosteum of the ulna.

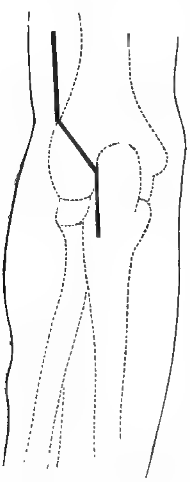

FIG. 3278.—Ollier's Incision.

Ollier employs the "bayonet" incision (Fig. 3278) as calculated to do the least injury to the soft parts. It is made thus:[18] Commence the incision on the external border of the arm six centimetres above the line of the articulations; carry it down to the level of the prominence of the epicondyle; thence turn it downward and inward to the olecranon. The direction of the knife is again changed and follows the posterior border of the ulna for four or five centimetres according to the amount of bone to be removed. This last part may be carried at once to the bone. Above the aponeurosis should be divided and the incision carried between the triceps on the one side and the supinator longus and the extensor carpi radialis longior on the other. The division of the capsule follows the external incision. The oblique part of the latter corresponds nearly to the interval between the triceps and anconeus. The internal lip of the wound with the triceps is detached, the connection of the tendon with the periosteum being carefully preserved. The external condyle is then cleared, the humerus luxated backward, the denudation completed, and the bone saw off. The bones of the forearm are then denuded and divided with saw or cutting forceps. It is usually better to begin with the radius.

When the operation is done for anchylosis Ollier sometimes finds it necessary to make a long radial incision and a small one on the ulnar side. The bone is sawn from behind forward nearly through and broken. This procedure somewhat resembles that of Hueter given below.

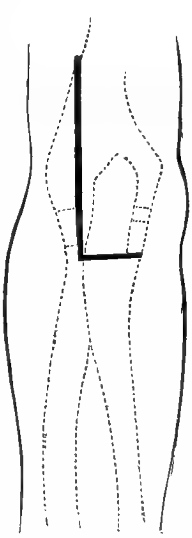

FIG. 3279.—Nélaton's Incision.

Nélaton used a radial incision with a transverse cut across the olecranon (Fig. 3279). The head of the radius is first exposed and sawn off. The olecranon is then denuded and the triceps tendon detached. The forearm is bent inward, the ulna protruded and sawn. The humerus is then easily protruded, denuded and sawn.

Hueter,[19] to avoid the division of the triceps tendon and facilitate the enucleation of the olecranon without disturbing the relations of the tendon to the periosteum and fascia, used the following method. A preliminary longitudinal incision (Fig. 3280), about half an inch in length, is made over the prominence of the internal epicondyle, or rather more in front to more certainly avoid the ulnar nerve. A circular cut around the base of the epicondyle detaches the muscles and divides the internal lateral ligament. The principal incision is made on the radial side. The knife is entered above the external epicondyle and carried straight down over that prominence, opening the joint and exposing the head of the radius, the lateral ligament being divided longitudinally and the annular ligament transversely. The head of the radius is easily freed and sawn off with the keyhole-saw and extracted. The left forefinger is then passed into the joint and the anterior part of the capsule made tense while it is detached from the bone with the knife or elevator. The finger is then passed behind, stretching the triceps tendon, which is detached in the same manner. It is not easy to clear the inner border of the humerus in this way, but by forced abduction of the forearm the ulna is dislocated inward and the humerus thrown out of the wound, where it is easily denuded as far as necessary and sawn off. The ulna is then brought into the centre of the incision, examined, and the triceps separated from above downward by short firm strokes of the knife or elevator, and the olecranon shelled out of its fibrous envelope until the necessary amount is denuded, when the bone is sawn.

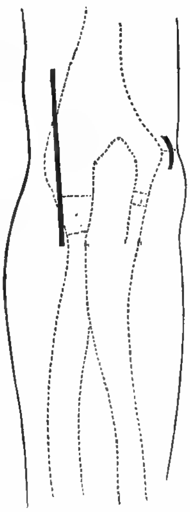

FIG. 3280.—Hueter's Incisions.

Von Bruns, as early as 1858, proposed osteoplastic resection of the elbow, by making use of temporary division of the olecranon, the sawn surfaces being reunited at the close of the operation. Originally this device was directed to the management of ancient dislocations or to compound dislocations. Other German operators have extended the use of the osteoplastic method to resection for foreign bodies in the joint, and have even employed it in operations for disease. This last application has been, by some surgeons, held to be unwise, owing to the frequency of disease of the olecranon, but there seems to be no impropriety in making section of the olecranon in doubtful cases, and removing the diseased bone entirely, if, after inspection, this course seems to be preferable. The methods employed for osteoplastic resection have been various, but the two given are as simple and apparently as successful as any. Fig. 3281 shows the incision of Von Mosetig-Moorhof.[20] The elbow being slightly bent the incision is carried from the lowest point of the external condyle across the base of the olecranon to its inner margin. From the end of this cut another runs at first parallel to the inner margin of the olecranon, and then curves slightly inward to a point about a finger breadth above the tip of the bone. The ulnar nerve is dissected out and drawn aside, the olecranon divided and turned up in the flap. The humerus is cleared and sawn off below the epicondyles, the head of the radius taken off, the olecranon scraped to sound tissue, and its sawn surfaces reunited with silver wire.

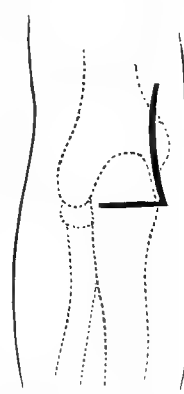

FIG. 3281.—Von Mosetig-Moorhof's Incision.

Stimson[21] avoids meddling with the ulnar nerve by combining the lower two-thirds of Ollier's incision with a transverse one across the base of the olecranon (Fig. 3282), and sawing the latter somewhat obliquely, from below upward, into the joint. The joint is then further opened through the lateral incision, the external condyle denuded and the flap, including the upper part of the olecranon, turned upward and inward. The humerus is then denuded and

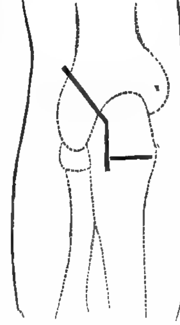

FIG. 3282.—Stimson's Incision.

sawn off through the epicondyles, the radius protruded and sawn through the neck, the diseased part of the ulna scraped, the capsule dissected out, and the parts of the olecranon reunited by silver suture.

It will be noticed that while many of the older operations, Liston's, for instance, were upon the ulnar side, and Langenbeck's is central, that the majority of the more recent operations, if not bilateral, are mainly upon the radial side.

In operating for anchylosis, if the union can be broken up, and frequently where it cannot be, the single incisions will usually suffice. Occasionally bilateral incisions are called for. Many operations have been devised, and methods for meeting the indications of special cases, but space forbids detailing such.

The after-treatment is important. The position preferable is that of very slight flexion, or perhaps, as Roser urges, for some time in extension, as giving more compact restoration of the soft parts. No splint is more generally acceptable than a well-applied gypsum bandage, bracketed or not, as the condition of the wound may render desirable. At first a very firm antiseptic dressing may suffice in place of splint. In the very young early motion is advisable, but in adults there is much less danger of anchylosis than of flail-joint, and passive motion may be delayed until a moderate degree of firmness in the tissues has been reached.

Resection of the Wrist.—The earliest operation of this kind known was for injury, Mr. Cooper, of Bungay, having, in 1750,* removed the lower ends of the radius and ulna for a compound dislocation. In 1762 Bagieu excised the joint for gunshot wound. The first resection for disease was in 1794, when the elder Moreau performed it. Operations were few until about 1840, since which time they have been more frequent. Nothing has ever done so much to establish the operation as the paper of Mr. Lister,[22] published in 1865, detailing an improved procedure, and giving the encouraging results of fifteen cases in which he had employed it. Resection of the wrist, however, has never enjoyed the popularity among surgeons that has been accorded to similar operations on some other joints. No one to-day would endorse Malgaigne's wholesale condemnation, but many grant the operation but limited approval. This is not due to a high death-rate, for, according to Culbertson,[23] the mortality proper to the operation for all causes is but 1.73 per cent. The failure of the resection in many cases to arrest the local process, or to hinder the development of kindred maladies, and the frequent worthlessness of the hand when saved, are responsible for this distrust. A glance at the anatomy of the wrist will show that the complex synovial sacs, and their relations to the many small bones, and the proximity of the numerous tendinous sheaths, favor the spread of disease and hinder its extirpation, except by an extensive and careful operation; while prolonged suppuration would very probably set up such adhesions of tendons as to permanently destroy the usefulness of the remains of the hand. Until a comparatively recent time, surgeons had not the technical resources to satisfactorily deal with the problem. It seems, too, that the operation has not been quite fairly dealt with, in that a tendency is shown to compare the functional results obtained with the perfect hand, and not, as should be done, with those of other operations, such as scooping or amputation.

There has been an unusual want of agreement among writers as to what constitutes a complete, and what a partial, resection of the wrist. Strictly speaking, the wrist means the radio-carpal articulation, but by extension it has come to include in this connection both the medio-carpal and the carpo-meto-carpal articulations as well. The most reasonable definition seems to be that a complete resection of the wrist must include the removal of the lower articular extremities of the bones of the forearm, or at least of the radius on the one side, and of the first row of carpal bones, except perhaps the pisiform, on the other. More may be removed in a complete resection, but less would make it partial, *i.e.*, to be complete both members of the radio-carpal joint must be removed.

Results.—The functional results of wrist exsection are very often very vaguely stated by reporters. So far as they can be separated, they may be divided into bad, indifferent, and satisfactory. By "bad" is intended that the limb is worthless and was subsequently amputated; by "indifferent," a hand of limited usefulness, the impaired mobility of the fingers preventing any work demanding delicacy or strength; by "satisfactory" is meant that there is mobility of all the fingers, that the opposition of the thumb is preserved, and that the person can write, sew, and do similar things requiring dexterity, and that, in some cases at least, the hand has sufficient strength for more laborious work, such as driving, the use of moderately heavy tools, or for the support of several pounds weight. In Culbertson's extensive tables of 58 excisions for gunshot wounds, 1 gave "perfect" result; 16 "useful" hand; 8 "not useful;" 2 "amputated;" 31 "not stated." Of 14 operations for injury, 4 are "perfect;" 8 "useful;" 2 "not stated." Of 79 operations for disease, 6 are "perfect;" 36 "useful;" 11 "not useful;" 10 "amputated;" 16 "not stated." These were all, or nearly, done without aseptic precautions.

Nepveu[24] has collated the final results in 36 cases, some of which are more recent than those in Culbertson's table. In 8 cases the result was absolutely bad, in 13 indifferent, in 15 really satisfactory.

Ollier[25] thinks that even better results than those usually considered "satisfactory" should be looked for. One of his patients, from whom he removed all the carpal bones but the pisiform, the articular surface and styloid process of the ulna, lower extremity of the second, fourth, and fifth metacarpal bones, and the whole of the third with its finger, two years after the operation could hold out at arm's length, for some seconds, a weight of ten kilogrammes—about twenty pounds. A second traumatic case, after eleven years, held out eleven kilos and was skilful on the trapeze, played the cornet, and was employed as a notary's clerk, writing all day without fatigue. In the latter case the operation was done for gunshot injury, the shot passing transversely through the wrist and severing the radial artery.[26]

Experience in the field has not been very encouraging, but nearly all of the records are based upon experience previous to 1865, before which date the status of the operation, as to technique and in other respects, was unfavorable to success. In the War of the Rebellion, of six complete excisions of the wrist, one proved fatal after recourse had been had to amputation in the forearm. The five others recovered with functions of the hand much impaired, but, all things taken into consideration, in a better condition than if they had been subjected to amputation.[27]

Gurlt's tables show that, of recovered cases of resection of the wrist in military surgery, none belong to his class of "very good;" 6.25 per cent. were "good," 50 per cent. "medium," 37.50 per cent. "bad," 6.25 per cent. "very bad." The same authority gives the mortality of primary resection as 10.25 per cent.; intermediary, 30 per cent.; secondary, 22.22 per cent.; total mortality in 126 cases, 16 per cent.

Partial excision, and mixed operation in which portions of the hand were removed, gave but indifferent results on the whole; but even these imperfect members, especially with proper supports, were usually more useful than the stump of amputation could be made to be.

Resection for anchylosis of wrist has been done. The one case (Langenbeck's) of which this writer knows the result was not successful, the anchylosis recurring.[28]

In general, anchylosis is frequent and flail-joint rare. The hand in many cases is distorted toward the radial side. Both the anchylosis and distortion are probably largely due to incomplete after-treatment. Dorsal flexion is naturally usually imperfect, owing to the normal predominance of the flexors over the extensors. It is asserted by some German authorities that soldiers some-

* This date is given in some books; Gooch, in 1767, alluded to the operation as occurring "many years ago."

times wilfully neglect after-treatment, lest their pension should be diminished.

Indications.—For injury, as compared with amputation, resection is always to be preferred, unless hopeless damage has been done to the tissues, especially to vessels and nerves. In civil practice the prognosis is excellent as to life, and as to function, it should always be remembered that a very indifferent hand is much better than none. There is good reason to believe that, with the simplification of aseptic dressings, very much better results can now be expected in military practice than heretofore.

In military surgery informal resections are now thought to be preferable. But nowhere is great attention to detail, the removal of hopelessly detached fragments, cleansing, tendon suture, etc., more necessary than in these operations.

In compound fractures and in compound dislocations the same careful informal operations are to be preferred.

For disease (caries) resection is indicated if expectant treatment has failed, but the rule is to be applied here with more limitation than to some other joints. Practically, resection is never called for during the first five years of life, and rarely before puberty, as less formal or less extensive operations take its place. In very young children the actual cautery, used through fistulæ or carried down knife-wise into the boggy and fungous tissues, is often followed by a marked improvement, with retrogression of the fungoid changes. Still later, *i.e.*, until about the age of puberty, the excavation of diseased parts by the scoop or periosteotome (conjoined with the actual cautery in parts which cannot be easily reached, or which the operator prefers to leave untouched by the instrument), and free drainage and compression, are followed by the happiest results and, probably, by more useful hands than could have been gained by formal resection. This last method, however, should not be made to include too niggardly openings. Sufficient room should be allowed for proper inspection of the parts, etc. After puberty, and during the first half of life, resection in form has its best results. The excavation may still succeed, but its special province is during the growing period of bone, while it still has great reparative vitality. After thirty-five or forty years resection is not forbidden, but its functional results are less brilliant.* The existence of caries of the carpus in adult life is often associated with tuberculosis elsewhere. This is generally considered as a contra-indication of resection, but in young adults resection is not rarely followed by a recession of pulmonary signs, and the operator must critically examine the history of the case as to the probable dependence of the general condition upon the local one, before deciding between resection or amputation. The existence of fungosities in the sheath of the tendons in adult cases is generally considered a strong contra-indication of resection, owing to the small chance of good functional results.

Operative Methods.—The back and sides of the wrist contain no important vessels or nerves, and the skin and tendons only overlie the joint structures. All operations on the joint are therefore preferably begun from these aspects. The radial artery winds into the dorsal aspect, but can be usually managed without damage. The injury done, in the older methods of excision, to the extensor tendons both by the operation itself and the prolonged suppuration, is largely accountable for the poor results obtained. At present the longitudinal incisions, single or double, have practically displaced all others; and the admirable method of Mr. Lister is by far that most frequently employed, at least by English-speaking surgeons. Although the case which seems first to have fixed Mr. Lister's attention upon the subject was a traumatic one, his paper is confined to the consideration of excision for caries. The description below is slightly abbreviated from this paper.[29] The operation elaborated by this great surgeon avoids most dexterously the chief difficulties of wrist-joint excision.

Before the operation is commenced, any adhesions of the tendons are thoroughly broken down by freely moving all the articulations of the hand. The radial incision is then made in the situation indicated by the thick line (L L) in Fig. 3283. This incision is planned so as to avoid the radial artery, and also the tendons of the extensor secundi internodii pollicis and indicator. It commences above, at the middle of the dorsal aspect of the radius, on a level with the styloid process, this being as close to the angle where the tendons meet as it is safe to go. Thence it is at first directed toward the inner side of the metacarpo-phalangeal articulation of the thumb, running parallel in this course to the extensor secundi internodii; but on reaching the line of the radial border of the second metacarpal bone, it is carried downward longitudinally for half the length of the bone. The soft parts at the radial side of the incision are next detached from the bones with the knife guided by the thumb-nail, so as to divide the tendon of the extensor carpi radialis longior at its insertion into the base of the second metacarpal bone, and raise it, along with that of the extensor carpi radialis brevior previously cut across, and the extensor secundi internodii, while the radial artery is thrust somewhat outward. This prepares the way for the next step, which is the separation of the trapezium from the rest of the carpus, by means of cutting forceps applied in a line with the longitudinal part of the incision—a procedure which, as experience shows, does not endanger the radial artery. The removal of the trapezium is reserved till the rest of the carpus has been taken away, when it can be dissected out without any considerable difficulty; whereas its intimate relations with the radial artery and its secure connections with the neighboring parts, would cause a great deal of trouble at an earlier stage of the operation. The soft parts on the ulnar side of the incision are now dissected up from the carpus as far as is convenient, the hand being bent back to relax the extensor tendons of the fingers. The separation of these is, however, best effected from the ulnar incision, which must be made very free. The knife is entered at least two inches above the end of the ulna, immediately anterior to the bone, and is carried downward between it and the flexor carpi ulnaris, and on in a straight line as far as to the middle of the fifth metacarpal bone at its palmar aspect. (Fig. 3284.) The dorsal lip of this inci-

* Gangolphe, De la Résection du Poignet, Revue de Chirurgie, 1884, p. 340, relates among others three successful cases at the ages of forty-six, fifty, and sixty-six years; one of whom was operated on after having refused amputation. Other cases of success, in spite of forbidding complications, are detailed.

sion is then raised, and the tendon of the extensor carpi ulnaris is cut at its insertion into the fifth metacarpal bone, and is dissected up from its groove in the ulna, care being taken to avoid isolating it from the integuments, which would endanger its vitality. The extensors of the fingers are then readily separated from the carpus, and the dorsal and internal lateral ligaments of the wrist-joint are divided; but the connections of the tendons with the radius are purposely left undisturbed. Attention is now directed to the palmar side of the incision. The anterior surface of the ulna is cleared by cutting toward the bone so as to avoid the artery and nerve; the articulation of the pisiform bone is opened, if that has not been already done in making the incision, and the flexor tendons are separated from the carpus, the hand being depressed to relax them. While this is being done, the knife is arrested by the process of the unciform bone, which is clipped through at its base with pliers. Care is taken to avoid carrying the knife further down the hand than the bases of the metacarpal bones; for this, besides inflicting unnecessary injury, would involve risk of cutting the deep palmar arch, the position of which is shown in Fig. 3285. The anterior ligament of the wrist-joint is also divided, after which the junction between the carpus and the metacarpus is severed with cutting pliers, and the carpus is extracted by seizing it from the ulnar incision with a serviceable pair of sequestrum forceps, and touching with the knife any ligamentous connections that may remain undivided. The hand being now forcibly everted, the articular ends of the radius and ulna will protrude at the ulnar incision, and are carefully examined and treated according to their condition. If they appear sound or very superficially affected, the articular surfaces only are removed. The ulna is divided obliquely with a small saw, so as to take away the cartilage-covered rounded part over which the radius sweeps, while the base of the styloid process is retained. The end of the radius is then cleared sufficiently to permit a thin slice to be sawn off parallel to the general direction of the inferior articular surface. For this purpose it is scarcely needful to disturb the tendons in their grooves on the back of the bone, the bevelled ungrooved part being enough to remove, and thus the extensor secundi internodii pollicis may never appear at all. The articular facet on the ulnar side of the bone is then clipped away with bone forceps applied longitudinally. If, on the other hand, the bones prove to be deeply carious, the pliers or gouge must be used with the greatest freedom. The metacarpal bones of the fingers are next dealt with on the same principle. If they seem sound, the articular surfaces only are clipped off, the little facets by which they articulate with one another being removed by the longitudinal application of the pliers.

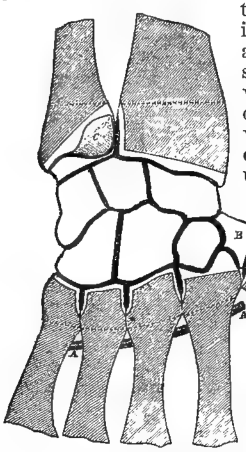

FIG. 3285.—A A, Deep palmar arch; B, trapezium; C, articular surface of the ulna, over which the radius moves.

The trapezium is next seized with a strong efficient pair of forceps, and dissected out so as to avoid cutting the tendon of the flexor carpi radialis, which is firmly bound into the groove on its palmar aspect, the knife being also kept close to the bone elsewhere to preserve the radial artery. The thumb being then pushed up longitudinally by an assistant, the articular end of its metacarpal bone is cleared and removed. Lastly, the articular surface of the pisiform bone is clipped off, the rest of the bone being left, if sound, as it gives insertion to the flexor carpi ulnaris, and affords attachment to the anterior annular ligament, and may serve other useful purposes in the palm. But if there is any suspicion of its unsoundness, it must be dissected out completely. The same applies to the process of the unciform. It may be observed that the extensors of the carpus are the only tendons divided; for the flexor carpi radialis is connected with the second metacarpal bone below its base, and so escapes.

The long single dorsal incision seems to have been used independently by several operators, but its use was made general through the influence of Langenbeck, and generally bears his name. His method is as follows: [30]

The hand is back upward and slightly bent toward the inner side. The cutaneous incision, beginning at the centre of the ulnar border of the metacarpal bone of the index-finger, is carried upward about four inches (nine centimetres), to the middle of the dorsal surface of the radial epiphysis (Fig. 3286). The incision is carried deeply on the radial side of the extensor indicis and without injuring its sheath, passing upward to the ulnar border of the extensor carpi radialis brevior (just at its insertion into the base of the third metacarpal bone). Here it divides the posterior annular ligament between the tendons of the extensor secundi internodii pollicis and the extensor indicis as far as the epiphyseal border of the radius. The incision being carried down to the bone, the soft parts, including the fibrous sheaths of the tendons, are lifted with the elevator and knife, together with the periosteum, the sheaths being unopened, first to the radial and then to the ulnar side of the incision. The hand is flexed so that the articular surfaces of the upper row of carpal bones are exposed. The scaphoid is liberated from the trapezium and trapezoid, and the semi-lunar and cuneiform from the os magnum and unciform by dividing the intercarpal ligaments, and gently lifted out with a narrow elevator. The trapezium and pisiform can be left behind [if sound]. The bones of the anterior carpal row are then taken out, the globular articular head of the os magnum is seized with the fingers of the left hand or a pair of vulsellum forceps, and while an assistant abducts the thumb the ligaments uniting the trapezium with the trapezoid are divided. The operator then tries to penetrate from here in a direction toward the ulna, into the carpo-metacarpal joints, by dividing the ligaments on the extensor side of the bases of the metacarpal bones, while an assistant forcibly flexes the latter. The trapezoid, magnum, and unciform can thus be lifted out together. The ends of the radius and ulna are carefully denuded, protruded, and sawn through in the usual manner.

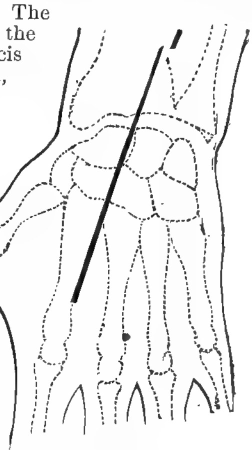

FIG. 3286.

Ollier urges the subperiosteal method. Although admitting that the wrist is not so good a field for this method as some other joints, he believes that the establishment of the "periosteo-capsular sheath" is useful in the repair. It hinders the changing of the relations of parts, and helps the forming of osseous or fibro-osseous masses which, although smaller than normal, are of value. They are irregular, and are bony grains "disseminated in an osseous gangue" which make the wrist firm but flexible. In one of his later articles,[31] Ollier claims that his opinion is based on the results of twenty-two personal cases of radio-carpal resection for osteo-arthritis, not counting partial ablations of the carpus and articular cauterizations in children. In addition he has had two primitive traumatic resections. After all the doubt arises whether the results, which in some cases were remarkably good, were due as much to the method of operation as to the very patient and pains-taking after-treatment.

The incision he formerly advocated [32] was on the radial side (see Fig. 3287). More recently [33] he has employed an incision much like that of Langenbeck, as follows :

The guides are an imaginary line connecting the styloid processes, the tendon of the extensor indicis, if recognizable, and the head of the second metacarpal bone. The patient lies upon his back, the hand extended and prone. An incision four or five inches long, commencing above the head of the second metacarpal, is made on the radial side of the tendon of the extensor indicis, and follows its direction until the bi-styloid line is reached near its middle. The cut divides the skin and subcutaneous tissue, a branch of the radial being drawn aside and the veins cut between two ligatures. Over the wrist the cut goes down to the periosteum and dorsal ligament, between the tendon of the extensor indicis and that of the extensor carpi radialis brevior. The annular ligament is divided and the tendons drawn widely apart. The articulation being open, all attachments on the dorsal surface of the carpus are separated by the sharp periosteotome (détachetendon), the carpus is dislocated backward by a movement of forced flexion, and the denudation of bone is continued on the palmar side until one of the bones can be extracted. Then, by the aid of the forceps and the periosteotome, the bones, one after another, are denuded and removed. The articular surfaces of the bones of the forearm are then examined, and if they must be resected, the incision is continued upward in the axis of the forearm, and making a slight angle with the first part. This incision reaches the bone between the tendons of the extensor proprius pollicis and the extensor indicis. The bones are denuded first toward the radial side as far as possible, the head of the ulna next, the bones dislocated and sawn.

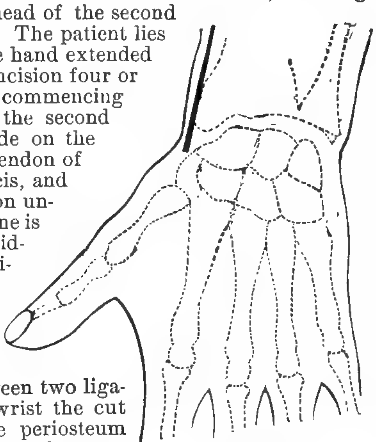

FIG. 3287.

After-treatment demands especially free and complete drainage of the wound. The palmar surface of the hand and forearm should be supported by a splint, the hand in dorsal flexion. Fig. 3288 shows Lister's splint. Plaster of Paris, or any other splint material, may be used if the points are kept in mind that the wrist shall be in dorsal flexion and the splint allow of early manipulation of the fingers. Early and persistent passive motion of the fingers is absolutely essential to success ; and faradism of the muscles of hand and forearm is of great service. Prolonged and painstaking care alone secures the best results.

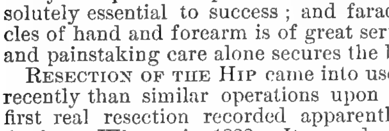

FIG. 3288.

RESECTION OF THE HIP came into use somewhat more recently than similar operations upon other joints, the first real resection recorded apparently being that of Anthony Whyte, in 1822. It was done for deformity, and the patient made a good recovery. The first operation for gunshot injury was done by Oppenheim, in 1829, during the Russo-Turkish campaign. The patient died of an intercurrent disease, plague or typhus. Resection for caries was performed by Brodie, in 1836, and perhaps by Hewson, of Dublin, in 1828, although the precise occasion of this operation is variously stated. Ferguson's operations, beginning in 1845, and those of some of his contemporaries, recalled professional attention to resection of the hip, and it thenceforward grew in favor until it took its place as an established procedure.

The discussion as to the value of resection has nowhere been warmer than in regard to the hip-joint, at least when done for disease. The matter will again be referred to under the head of Indications.

Strictly speaking, resection of the hip is "complete" only when the acetabulum is more or less involved in the operation, as well as the head of the femur. In this sense "partial" operations are commoner than "complete," and the mortality for the latter is somewhat higher than for the former, owing, doubtless, to the greater gravity of cases which demand interference with the acetabulum, rather than to the greater severity of the operative procedure.

Resection of the hip is done for gunshot wound, for caries, and, less frequently, deformity resulting from disease or injury. It has also been done for ancient dislocations of the hip, traumatic [34] or spontaneous,[35] for recent luxation with fracture of the neck,[36] for intracapsular fracture,[37] for congenital luxation of the hip,[38] for acute suppuration of the hip, and even for acute infectious osteomyelitis.[39] In a case of the last mentioned kind the writer once excised simply as a palliative measure to relieve suffering.

Results.—The mortality of resections of the hip for gunshot wounds has always been very high. Culbertson's tables make it 89.07 per cent., Gurlt's tables, 88.23; for cases in military practice only, 89.92 per cent. There is a singular agreement in the results in various wars, as, for instance, our own war gives 90.90 per cent., while the German war gives 90.56 per cent. Gurlt gives the following as the results of resections at different periods : Primary, 92.68 per cent. ; intermediary, 94.11 per cent.; secondary, 89.39 per cent. ; late, 60 per cent. These figures of mortality may be compared with those of amputation at the hip-joint and conservative treatment. Thus Otis states "that of the cases of undoubted intracapsular shot-fracture of the hip treated by conservation, 98.8 per cent. had a fatal termination ; that in 66 cases treated by excision the fatality was 90.9 per cent., and that in 66 cases treated by exarticulation it was 83.3 per cent. The high death-rate of resection, however, was modified by the fact that the operation was done in nine cases where the injury to the pelvis and viscera was found to be such that all interference was uselesss, and the numerical comparison, therefore, is not a just one. Further, of six cases of resection of the hip in the United States service since 1865, and reported by Otis, four recovered. Of the six recovered cases belonging to the War of the Rebellion, two could walk with a cane, one without support. In the other cases the limb was of little value. The results since 1865 were better. Gurlt gives for recovered cases "very good," 25 per cent.; "good," 75 per cent.

The mortality of resection of the hip, when done for disease, is very low, if death from the immediate results of the operation are considered. Culbertson's tables contain 418 cases, with 174 deaths, or 41.62 per cent. ; or, omitting uncertain cases, 44.84 per cent. Only 29 deaths, or 6.93 per cent., resulted directly from the operation, leaving 37.91 per cent. as the result of the progress of the disease or its complications. The most extensive statistics of antiseptic operations are those of Grosch,[40] who gathered 166 cases, 120 observed to the end, the mortality being 36.7 per cent. It will be noted that asepsis has practically annulled the mortality from operation. Grosch's results correspond closely with those of Culbertson, if operative deaths are left out.* The results of Grosch, König, Caumont, and others show that the mortality of hip-disease from tubercular complications has not been diminished by antiseptic surgery. That the death-rate of excised cases is greater than that of all cases of suppurative hip-disease treated by expectancy or conservatively, is not an argument against resection in proper cases, as the operation is usually applied only to the graver cases.

* The matter of statistics and of indications will be found discussed more at length in the writer's article in N. Y. Med. Journal, November 28, 1885.

Functionally, the results of resection for hip-disease cannot, statistically, be presented. Many cases have recovered with admirable limbs, mobile and stable. See, for example, Fig. 3289, from Sayre. But such cases are relatively rare. Many never really are healed, and many others are healed with limited motion, or without any. The precise percentage of each class cannot be given except for very small groups of cases. Hence the question has been debated, and, perhaps, as ably as by anyone, by Holmes,[41] whether the results of excision are, on the whole, as good as those of cures by anchylosis. To the writer it seems clear that the results of excision are not, on the average, as good as anchylosis in a good position. For the function of the lower extremity is support as well as locomotion. Security in the support of the trunk is, in most occupations, more important than mobility at any one joint. But this fact does not touch those cases in which a "natural" cure cannot be reasonably looked for. It is an argument only against precipitate and indiscriminate excision.

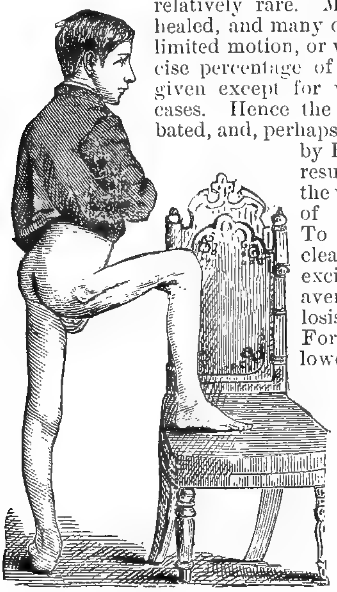

FIG. 3289.

Indications.—In military surgery Otis holds that primary excisions of the head or upper extremity of the femur should be performed in all uncomplicated cases of shot-fracture of the head and neck, that intermediary excisions are indicated in similar cases where the diagnosis is not made out till late, and that secondary excisions are demanded by caries of the head of the femur, or secondary involvement of the joint. These indications are influenced by the very high mortality attending conservative treatment. Langenbeck[42] finds the experience in conservatism during the Franco-German war to have been less dismal; he reports 25 recoveries against 63 deaths, and in nearly all of the recovered cases the diagnosis may be considered well founded. In view of the remarkable change in the prognosis of such injuries in civil practice, where antiseptic methods are used, it is impossible to accept the gloomy view of Otis as final; and where asepsis is possible in the field, it seems entirely proper to treat conservatively uncomplicated cases of shot-injury of the hip where little comminution exists, and the general condition of the patient is good. But in the majority of cases the rule for resection holds good.

For caries resection is indicated under the general rule, namely, whenever conservative treatment has failed or cannot succeed. As it has not been shown that, on the average, resection gives limbs more useful than natural cure, even after joint-suppuration, nor that, counting the period of after-treatment necessary to the securing of a good result, it materially shortens the duration of treatment, the indication remains entirely a vital one. If conservative treatment probably cannot save life or effect cure, operative procedures are indicated. More specifically, if a sequestrum or necrosis of the acetabulum or of the head or neck of the femur exists, resection is imperative; if pelvic abscess or advanced disease of the acetabulum is present, resection is the only alternative, even if only palliative; if, by reason of caries or inveterate disease of the soft articular tissues, suppuration persists and impairs the general condition in spite of treatment, resection is called for. It may be called for in the rather rare cases of caries with little suppuration and great suffering, the so-called caries sicca, to relieve pain. Early resection, with the intent to arrest coxalgia before conservative treatment has been fairly tried, cannot be considered as a necessary or advisable operation.

In acute suppuration of the hip, arthrotomy with drainage may obviate the necessity of resection, but an incision suitable to either operation should be made, and the decision left until after exploration.

Resection may be done for deformity when the latter is due either to bony or fibrous anchylosis, or to displacement of the upper extremity of the femur upon the dorsum ilii, with perhaps persistent sinuses. The operations for deformity have included not only resection of the hip joint or its remains, but of the upper part of the shaft of the femur as well as simple osteotomy of the femur. These all, however, are here included, as they are all used as means of rectifying the deformity resulting from hip-disease. Resections for dislocations not connected with hip-disease have been alluded to above. Operative interference for deformity is called for when the position of the limb is such as to make locomotion difficult, and when there is a reasonable prospect of improvement by operation; when, especially in women, the position of the limb makes cleanliness difficult, and causes much annoyance in connection with micturition, menstruation, etc.; also when the false position is attended with pain.

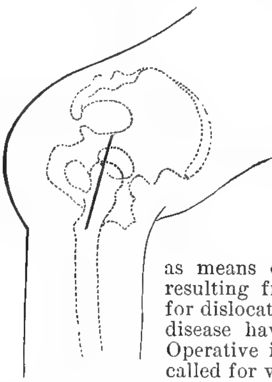

FIG. 3290.

Methods.—Owing to the relative simplicity of the hip-joint, its excision is not difficult. In the majority of operations incisions over or behind the great trochanter have been employed. The three best known are Langenbeck's, Sayre's, and Ollier's. They are all subperiosteal. The first (Fig. 3290) is made when the thigh is semi-flexed, by carrying the knife from the middle of the trochanter upward and backward in the line of the axis of the thigh, four or five inches toward the posterior superior spine of the ilium. The incision separates the fibres of the gluteus maximus, and divides the fascia lata and periosteum of the trochanter. The muscles inserted into the trochanter, front and back, are freed with the knife, their connection with the periosteum and fascia lata being preserved as far as possible. The capsule is then completely divided by strokes of the knife in the axis of the neck of the femur. The periosteum, with the capsular ligament and the insertion of the obturator externus, is separated all around the neck of the femur. The cartilaginous rim is divided, and a piece removed with the knife on both sides of the incision. The limb is adducted and inverted, dislocating the head of the femur; a narrow knife is thrust into the joint from behind, and the ligamentum teres divided. The head is protruded and sawn off. The trochanter is left if sound. The acetabulum is drained and the wound closed.

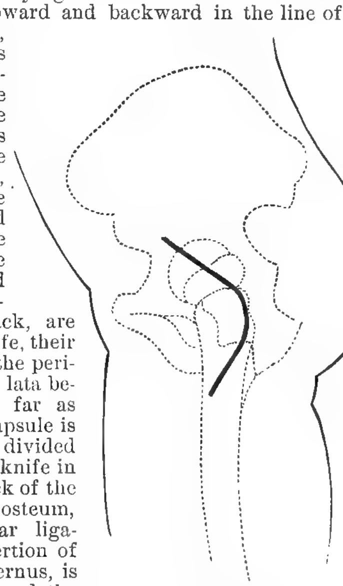

FIG. 3291.

Sayre's procedure probably is that most frequently em-

ployed in this country. It is as follows: A strong knife is thrust down to the bone at a point midway between the anterior inferior spinous process of the ilium and the top of the great trochanter. The knife, still firmly in contact with the bone, is carried in a curved line over the ilium across the top of the trochanter, midway between its centre and its posterior border, and then forward and inward, making the whole length of the incision from four to eight inches, according to the size of the thigh (Fig. 3291). This incision should divide the periosteum throughout; if it has not done so, the point of the knife must traverse the same course again until the division is complete. The wound is then held open with retractors, and with a narrow, thick knife a second incision is made through the periosteum only, at right angles to the first incision, about on the level of the lesser trochanter, or a little above it, and carried as far as possible around the bone behind and before. This makes the incision through the periosteum an inverted **T**. Beginning at the angles of the two incisions, the periosteum is raised with the elevator (Fig. 3248), before and behind. In the digital fossa the knife must be used to divide the muscular insertions, its edge being kept close to the bone. The elevator is then resumed, and the periosteum raised as far as can be done without breaking it. The limb is then slightly adducted, and the head of the femur lifted out from the acetabulum. This manœuvre detaches the periosteum from the inner side of the bone, and should be done without violence, and care should be taken to denude only so much bone as is to be sawn off. If this dislocation cannot be easily accomplished, saw the bone *in situ*, and detach the fragment by means of the forceps and elevator. The bone is removed by the keyhole- or chain-saw, the line of section being just above the trochanter minor. Dr. Sayre always removes the trochanter major, as he holds that its retention prevents free drainage of the wound. When the operation is made in childhood, the larger part of the trochanter is still cartilaginous, and is turned off with the periosteum from the diaphysis. If the disease extends below the line of section, the bone should be thrust out from its periosteum and again sawn. The acetabulum is then examined; if diseased, gouged or scraped; if perforated, all bone from which the internal periosteum is detached should be removed. The sinuses are cleansed.

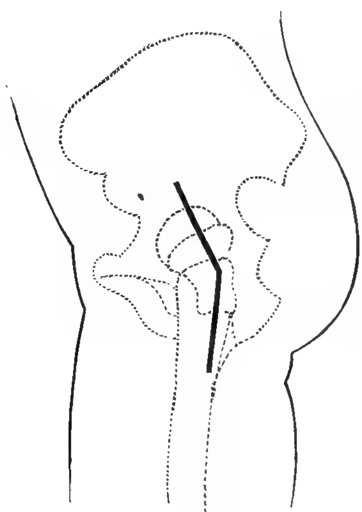

FIG. 3292.

Ollier's incision is made thus [43] (Fig. 3292): The thigh being slightly flexed on the pelvis, say to 135 degrees, the incision begins four finger-widths below the crest of the ilium and the same distance behind the anterior superior spine. It runs down and slightly forward in the direction of the fibres of the gluteus medius, to the prominent part of the great trochanter. It then changes its direction and goes forward and downward in the axis of the shaft of the femur. The posterior lip of the wound is drawn back, the tendon of the gluteus maximus crowded back with the elevator, and the gluteus medius exposed. This muscle is divided parallel to its fibres, dividing, not cutting, them. The gluteus minimus is treated in the same manner, and the capsule opened from the cotyloid border to the digital fossa of the trochanter. The muscular insertions are not separated from the periosteum. The head is pushed up, the round ligament cut, and the neck of the bone denuded as it is pushed up; when it is sufficiently exposed and protruded it is sawn off.

Ollier also makes use of an osteoplastic method.[44] The incision is curved convex downward, the centre being the lowest part, a fourth of an inch below the top of the trochanter, and the ends about an inch and a half (in an adult) before and behind the corresponding borders of the trochanter. The trochanter is exposed, sawn, or in childhood cut with a strong knife, at an angle of 45 degrees with the shaft, and the piece broken off and turned up; the head and neck are then denuded and removed, and the trochanter replaced and sutured to the shaft if none of the latter has been removed.

Langenbeck's operation seems to have been founded upon the requirements of an operation made for gunshot injury, while those of Sayre and Ollier are particularly applicable to operations for disease.

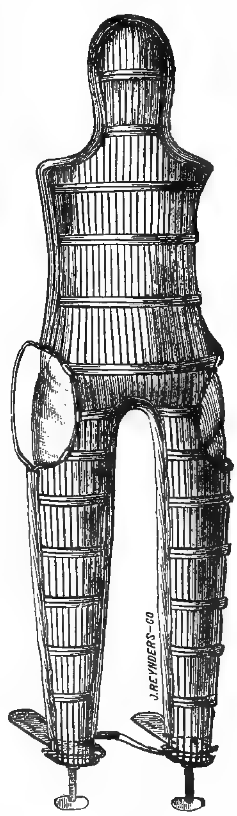

FIG. 3293.

Besides these methods many others have been proposed and employed. Thus Roser [45] recommends, in order to save the trochanter, a transverse incision from the outer side of the crural nerve to the root of the great trochanter. Lucke[46] and Shede[47] make a longitudinal anterior incision to the outer side of the crural nerve. R. W. Parker [48] makes an antero-lateral incision running from the anterior superior spine of the ilium downward and forward to the anterior border of the great trochanter. It enters between the tensor vaginæ femoris and sartorius on the inner side, and the two smaller glutei muscles on the outer, exposing the capsule. If this is not already open it is incised with a blunt-pointed curved bistoury, parallel to and rather inside of the anterior inter-trochanteric line. The neck of the bone is sawn *in situ* with a keyhole-saw and removed with the sequestrum forceps. The trochanter is left if not diseased. These anterior incisions seem to present little of advantage over the older ones, although, if suppuration is overcome by aseptic precautions, they may be safe. If, however, much suppuration occurs, they have the decided disadvantage of poor drainage. If sinuses already exist in the locality these incisions may occasionally be found useful.

Dr. Sayre dresses the wound by washing it out, filling it with Peruvian balsam, and stuffing it with oakum, the ends only of the wound being closed with stitches, and a tent of oakum in the middle serving for drainage. A layer of oakum is laid over the wound, and the limb neatly bandaged. He prefers to place the patient in the wire cuirass (Fig. 3293), which is previously well padded, and is fitted with extension screws at the feet. When a patient is firmly fixed in this apparatus, he can be moved with great ease without discomfort, and for very young and not very tractable patients it is a great convenience. Ordinarily, however, the usual antiseptic toilet of the wound may be used, and a firm antiseptic dressing with weight and pulley extension, make a very comfortable and satisfactory appliance. Fig. 3294 shows a good method of applying the antiseptic dressing.

When the wound is considerably consolidated, the question of passive motion is to be considered. If mo-

bility of the new articulation can be had in conjunction with stability it is very desirable, but if but one can be had, in nearly every walk in life stability is much the more

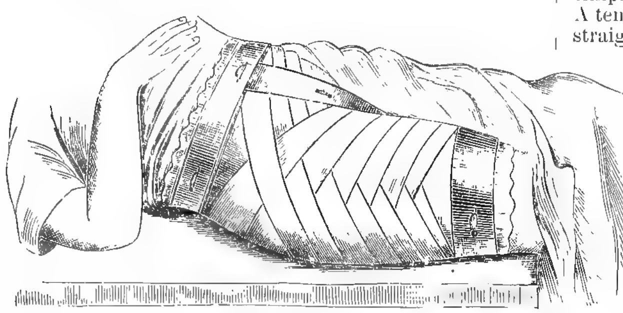

FIG. 3294.

desirable. It has been urged, therefore, by some observers of experience, that anchylosis after resection of the hip should be directly aimed at. If there is much destruction or necessary removal of bone this is probably the wisest plan but if the case gives hope of both, then passive motion may be begun after the parts are already moderately firm. For a considerable time, many months at least, the wearing of a support, such as the hip-splint (Fig. 3295), is of decided advantage in securing firmness of the forming new articulation.

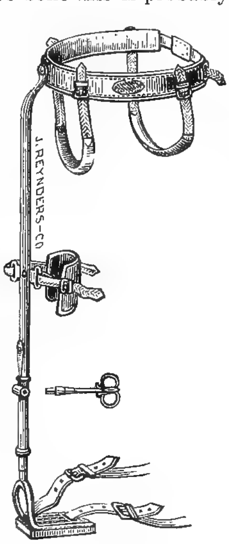

FIG. 3295.

Operations for Anchylosis.—Rhea Barton, in 1826, operated by resecting a **V** from the shaft of the femur, with a good result. Similar operations followed.

Sayre, in 1862, operated upon two patients for bony anchylosis of the hip.[49] The operation was essentially the same in both cases, and in the second case was as follows: An incision six inches long was made over the trochanter, as nearly as possible crossing its centre and going directly down to the bone. About the centre of this incision another at right angles was made, in the posterior flap, carried only through the broad fascia. The bone was then denuded with the elevator, first in front to the trochanter minor, and then behind till the finger could surround the bone, with the exception of a thin, firm fascia between them on the front. This was pierced by a bent steel sound, and a chain-saw carried around above the trochanter minor, which served as a guide. About half an inch above the trochanter minor the saw was carried through the bone, at first upward and outward, then outward, then downward and outward, making a curved section concave downward. The saw was again carried around the bone, and commencing about an eighth of an inch before the beginning of the first section, a second section was made at right angles to the axis of the shaft of the bone (see Fig. 3296). The wound was drained and closed. Extension by weight and pulley.

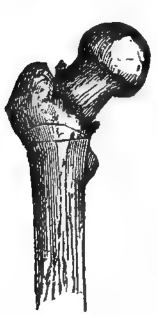

FIG. 3296.

In the first case the result was very satisfactory functionally. The second patient did well, and gained considerable use of the limb. About four months afterward was attacked with pneumonia and died tuberculous about six weeks later. A very good false joint had formed in this case.

Adams,[50] in 1869, operated for anchylosis by the much simpler method of osteotomy of the neck of the femur. A tenotomy knife was carried straight down from a little above the top of the great trochanter to the neck. A small saw (Fig. 3297) was inserted into the same track and the bone sawed through from before backward (Fig. 3298). Tenotomy of several muscles was necessary before the limb was brought into a straight position. Wound closed. Liston's splint. Anchylosis occurred in the improved position, but the limb was very useful. In some cases since operated upon motion has been preserved, at least for a time. Fig. 3299 shows Dr. Shrady's very convenient instrument for making this and similar operations. It consists of a trocar and fenestrated cannula, and a saw fitting the same cannula. In use the trocar is thrust to the point which is to be sawed. The trocar is then withdrawn, the cannula being left in position, the screw-button on top, on the side opposite to the fenestra, being a guide to the position of the latter. The saw is then introduced through the cannula, and the section made without danger of wounding any parts except those intentionally divided.

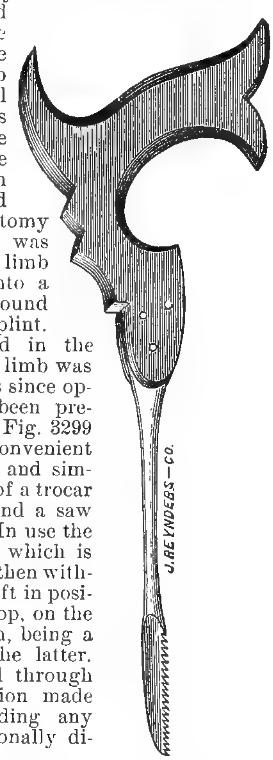

FIG. 3297.

Volkmann, who formerly advocated sub-trochanteric osteotomy to correct deformity, has devised[51] a "chisel resection" for anchylosis at the hip. The incision is Langenbeck's (see ante). The great trochanter is cut nearly through about an inch below its summit, and the inner wall of the neck of the femur broken through. The inner side of the end of the shaft is rounded with chisel and rongeur until it is about as thick as the middle of the shaft. It is better to remove too much than too little. An acetabulum is then worked out with the gouge large enough to permit free motion of the new head. Antiseptic dressing. Strong extension by weight very long continued, and very persistent passive motion. For most cases Volkmann still prefers osteotomy, especially if the limb be short and atrophic. He considers the chisel resection indicated (1) when the anchylosis is double; one side should have an osteotomy for security, and one resection for locomotion; * (2) when it is not absolutely certain that the disease has been suppressed; (3) in great displacement of head of femur make osteotomy, and resect if necessary to bring bony surfaces together.

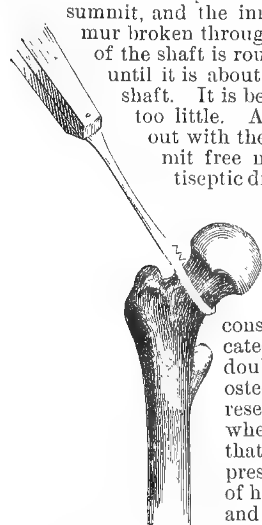

FIG. 3298.

RESECTION OF THE KNEE has an especial historical interest in that upon this joint the operation was first done for disease by Filkin (1762), and again, apparently independently, by Park (1781), who

* This suggestion has been carried out (Mordhurst, Archiv f. Kl. Chirurgie, xxxi., 677).

first in modern times proposed the operation of resection as a formal method of treatment of diseased joints instead of, as previously it had been, an extemporaneous means of meeting emergencies, such as compound dislocations. In spite of the distinct advocacy of Park and the Moreaus, the operation was slow in gaining ground, and previous to 1850 the recorded operations were few, Culbertson giving but 54 out of a total of 745 in his tables. The revival of the operation was due chiefly to the endeavors of Textor in Germany, and Fergusson in England.

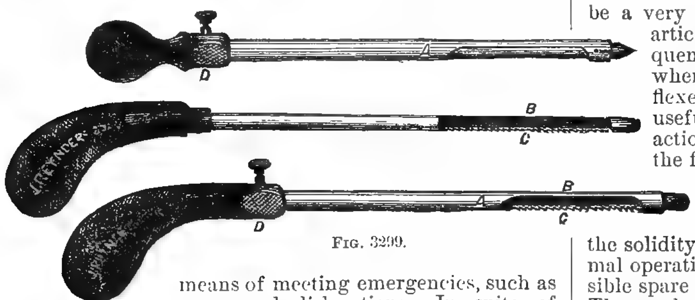

FIG. 3299.

In order that a resection of the knee may be considered *complete*, the articular surfaces of both femur and tibia must be removed; if one of these surfaces be left, however extensive the operation in other respects, it is still *partial*. The removal of the patella is not considered necessary to make the resection complete. As of other joints, resection of the knee is done for gunshot wound and other injuries, for disease, and for deformity.

Results.—The results of resection of the knee for gunshot injury have been discouraging, owing to the high mortality. Culbertson's tables show a death-rate of 75 per cent., or for hospital cases alone, 87.5 per cent. Otis gives for the War of the Rebellion a mortality of 81.4 per cent., which is much higher than the mortality of amputations at the knee-joint—56.6 per cent.—or for thigh-amputations for knee-injury—50.9 per cent. The same authority,[52] collecting cases from all sources, gives the mortality after conservative treatment as 57.3 per cent. when there was fracture of the joint-bones, and 21.9 per cent. when the wound did not involve the bone. Culbertson also gives the mortality of resection done for injury other than gunshot at 39.28 per cent., for disease at 25.32, for deformity at 13.2. A. M. Phelps[53] has tabulated 329 cases of antiseptic excision of the knee with 31 deaths, or 9.42 per cent., or (deducting 15 cases of phthisis, 1 ether death, 2 amyloid disease, 2 nephritis, 1 poisoned wound) 10 deaths properly due to operation, or 3.03 per cent. Likewise Bergmann reports excellent results for wounds of the knee-joint under antiseptic dressing (of wounds not involving bone out of 21 cases 18 recovered; 3 under treatment).

Culbertson shows that age influences mortality. The mortality of operations for disease under five years of age was 38.88 per cent.; from five to ten years, 16.19 per cent.; from ten to fifteen years, 17.17 per cent.; fifteen to twenty, 30.11 per cent.; twenty to twenty-five, 39.39 per cent.; twenty-five to thirty, 37.3 per cent.; thirty to forty, 41.55 per cent.

As to function, after recovery from resection for gunshot wound, 58.8 per cent. of limbs were reported "useful;" 23.8 per cent. were subsequently amputated (Culbertson). According to Gurlt (German wars from 1848 to 1871), 55.55 per cent. of limbs were "very good;" 33.33 per cent. "good;" 11.11 per cent. "very bad." "Perfect" or "good" results followed operations for injury in 82.3 per cent. of cases; for deformity in 87.3 per cent., and for disease in 56.7 per cent.

The functional failures are due in some cases to the destruction of the epiphysial cartilages. As is well known, the femur grows chiefly from its lower epiphysis, and the tibia from its upper one. If in childhood one or both of the epiphyses are totally removed the shortening of the limb may be excessive. Other failures arise from non-union or imperfect union of the sawed surfaces. Usually in resection of the knee anchylosis is aimed at. It is now known that without bony union, or even with considerable motion at the false articulation, the limb may be a very useful one; but great stability of the new articulation is necessary to good use. It not infrequently happens, and particularly in children, that when the limb is walked upon it gradually becomes flexed at the knee to such a degree as to destroy its usefulness. This flexion is due to the combined action of the weight of the body, the traction of the flexors of the legs, and, it is believed, by the greater growth of the anterior part of the epiphysis. The two forms of failure have led to various technical devices to increase the solidity of the union, on the one hand, and to informal operations, on the other, which should as far as possible spare sound tissue and preserve the joint functions. The results of informal operations cannot be statistically stated, but they seem, from reported evidence, worthy of trial in favorable cases, even if, as some claim, relapses demanding subsequent excision sometimes occur.

Indications.—Resection for gunshot injury in military practice has proved so fatal that unless aseptic surgery shall give better results it seems hardly to be indicated at all. Such improved results are still wanting. Gunshot wounds of the knee without fracture seem, in the light of the latest experience (Bergmann) to do well without operation if antiseptically treated. If fracture exists, amputation is still the safest alternative.

In fungous disease operative interference is indicated whenever such expectant treatment as the patient can command has failed to improve the condition, especially if there is a persistent suppuration, and in any case in which the functions of the joint seem to be hopelessly impaired, inasmuch as the anchylosis necessary to a useful limb can be much more quickly reached by antiseptic operation than by the tedious process of natural cure. Fungous disease presents peculiar features at the knee, notably in the relatively less extensive bone-lesions and the predominant fungous synovitis. The peculiar, sluggish course of "white swelling" renders interference proper without open suppuration or certain bone-disease. There is also a greater latitude of choice as to kind of operation than is usual at other joints; namely, between arthrotomy, arthrectomy, resection more or less complete, and amputation. Arthrotomy, so valuable in acute joint-inflammations, has not proved equally efficient in fungous disease. The distinction between arthrectomy and true resection is not a very hard-and-fast one, inasmuch as, besides the extirpation of the diseased soft tissues, all diseased bone is gouged away, and although the typical forms are departed from, the resection may be as extensive as in the most formal procedure. If by resection the formal operation alone is meant, it seems to be less frequently indicated than formerly was supposed. In very young children, under five years of age, it is not called for; in older children the informal operations will probably give at least as good results. Resection gives the best results, all things considered, in the age of adolescence, and next in early adult life. At this time of life the form of operative interference to be preferred is usually resection. The results become less satisfactory later on, and the choice between resection and amputation less clear; after middle life, most surgeons prefer amputation.

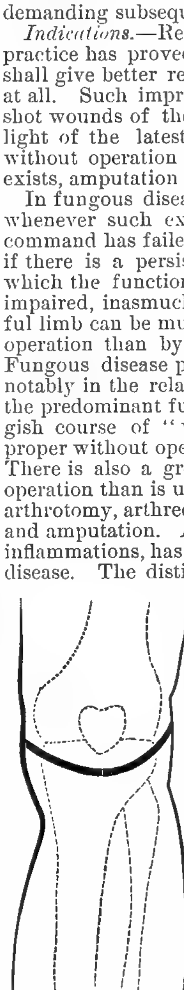

FIG. 3300.

Methods have been for this joint also very numerous. But the semilunar incision, convex downward, the **H**, and the transverse in its several varieties, are much the most frequently employed.

If in a typical resection the semilunar incision (Fig.

3300) is employed, the knife enters at the back part of one condyle and is carried somewhat downward, and crosses below the patella, and is carried to the back part of the other condyle. The point of the knife should be carried to the bone throughout its course, and divide the ligamentum patellæ. It may sometimes also divide the lateral ligaments. The flap is turned up, exposing the joint freely. The knife, kept close to the tibia, divides the crucial ligament, and section of the lateral ligaments is completed. The lower end of the femur is then cleared, especial care being used at the back of the bone to avoid wounding the vessels. The femur is now protruded and a thin slice, carrying the articular cartilage, is sawed off. Figs. 3301 and 3302 (from Holmes) show the relation of the ordinary saw-cuts to the epiphyseal cartilages. If it be possible to avoid it, these cartilages should not be touched; diseased parts only should be removed. The saw would better be carried not quite through the bone, but the last part broken away to prevent danger to the popliteal vessels and nerve, the rough edges of the bone being subsequently smoothed. In sawing the femur the cut should be parallel to the articular surface, and should remove an equal amount from both condyles. The tibia is cleared and sawed in the same manner. There is a decided variance of opinion about the removal of the patella, some operators preferring to keep it as an extra strength to the anchylosis, and as preventing the tendency to flexion which is quite common, especially in children; others preferring to take it away, as being of little use and a possible source of renewed disease. The writer shares the latter opinion, and believes that if in a typical resection the patella is to be left, its inner surface should be shaved off, so that a better judgment of the interior condition of the bone can be formed, and in order to insure its closer union to the other bones. The diseased synovial membrane is scraped or cut away, and all suspected parts of bone gouged.

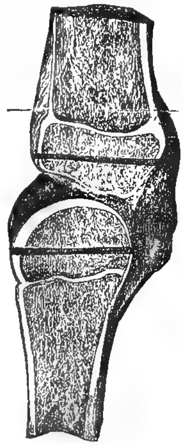

FIG. 3301.

If the transverse cut is used it may be just below the patella, and transverse to the axis of the tibia, in which case, as Ashhurst points out, if the knee is bent at the time of cutting, the incision becomes a semilunar one when the limb is straightened, and much like that already described. It may be made above the patella, giving convenient access to the upper pouch of the joint. Or, again, it may be made directly across the patella, at or slightly below its centre. If lateral offsets be added it becomes the **H**-incision, the upper and lower flaps being dissected and the remainder of the operation being as described for the semilunar incision. The incision across the patella was proposed by Volkmann, and has been considerably employed. It begins at the anterior border of one epicondyle and passes directly across the middle of the patella to the anterior margin of the other epicondyle. The joint is then opened on either side of the patella, the index-finger is thrust under the patella on either side for exploration, and if the operation is to proceed the bone is sawed across, the lower fragment turned down, and the joint cleared. The operation is to be finished as usual. This method facilitates extirpation of the joint. The section of the patella allows a judgment of the condition of that bone. If it is sound, it is left either entirely or with its inner surface shaved off. The fragments are then reunited by suture. Besides, Ollier recommends that for traumatic resections the patella be divided vertically in the course of a median longitudinal incision. Langenbeck made a subperiosteal resection through an internal semilunar incision, the convexity behind passing over the posterior part of the internal condyle. Ollier also urges the subperiosteal method, and formerly used the external anterior incision shown in Fig. 3303. He has more recently [54] recommended a small **H**-shaped incision, the lateral cuts converging below, together with lateral posterior drainage-openings made before the parts are removed. The patella is not retained, and section of the lateral ligaments is avoided if possible.

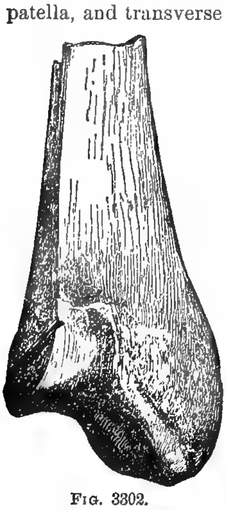

FIG. 3302.

Among modifications to secure greater fixation may be mentioned that of Neuber, who used the semilunar incision, and besides the usual resection of the articular surfaces trims off the posterior prominences of the condyles, shaves off the front of the tibia and femur, and the posterior surface of the patella. The femur and tibia being nailed together, the patella is nailed to their shaved surfaces so as to act like a clamp to hold the main bones in apposition. Fenwick [55] also uses the semilunar incision and follows the customary method until the bones are to be sawn. A fine fretwork saw, in a butcher's saw-frame, is then carried in a circular sweep over the condyles from before backward removing the cartilage and all diseased bone, both condyles being diminished equally, and the end of the femur is left rounded in an antero-posterior direction. The tibia is sawed from behind forward, with a concavity to fit the convexity of the femur. The patella is removed. Kocher [56] seems to employ nearly the same method.

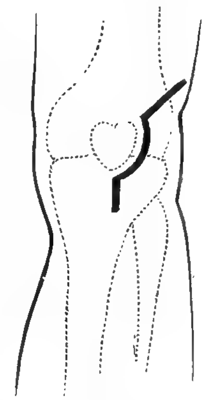

FIG. 3303.

A. M. Phelps urges resection of the hamstrings as a safeguard against subsequent flexion.

If arthrectomy is intended, it is well to choose an incision which will serve for resection if, after exploration of the joint, the latter operation seems to be preferable.

The operations for deformity are cuneiform osteotomy above the condyles (Rhea Barton); simple osteotomy of the femur, and of the femur and the leg bones (Barwell); removal of a wedge, including site of knee-joint (Buck), and breaking up of anchylosis followed by resection. If there is any doubt as to the persistence of disease at the joint, resection of the joint itself is the only operation. If the flexion is above a right angle, reduction of the deformity will probably demand the removal of a block of bone which is not a perfect wedge, *i.e.*, which has some thickness behind. The technique has nothing peculiar. Any convenient incision may be used, the **H** or the semilunar being usually most convenient. It is thought to be safer to break out the block or wedge before the entire thickness of the bone has been cut, and to finish with a chisel, gouge, or other convenient instrument.

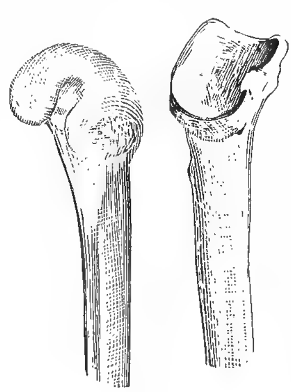

FIG. 3304.

It is usual to fasten the femur and tibia in apposition by sutures of wire or of catgut, or by nails or pins of bone. It is not necessary to use anything if the shape of the

sawn surfaces, as in Fenwick's method, for instance, is such as will, with the help of a firm dressing, maintain the juxtaposition. It is not absolutely necessary in the ordinary forms of operation,[57] but some such device is valuable to prevent the thigh from rotation outward, while the tibia remains in position, which results in a bad intoeing when the limb is otherwise fit for use. The methods of introducing wire and nails have been described. Additional firmness is gained by deep stitching of the soft parts.

The drainage should be from the posterior lateral angles of the wound, from the superior pouch, and other dependent points if necessary.

The antiseptic dressing is usually followed by a splint. Various devices have been satisfactorily employed, but for ordinary cases a good plaster bandage, fenestrated and bracketed, answers all purposes. A long anterior rod, shaped to the limb, bent at the knee into bracket-shape, and continued upon the dorsum of the foot, with

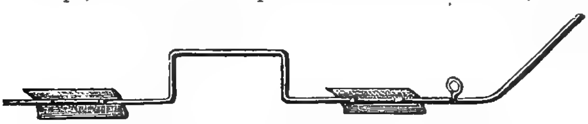

FIG. 3305.

rings for suspension (see Fig. 3305), as recommended by Watson, is an excellent addition to the plaster dressing. Suspension of the limb is usually comfortable, and prevents or diminishes the danger of displacement of the fragments if the patient changes his position. Subsequent dressings should be as infrequent as surgical cleanliness will allow, and the seat of operation be disturbed as little as possible.

The time requisite for union varies greatly, but is much shorter with antisepsis than without. Patients are confined to bed sometimes only a month, but usually a considerably longer time is required.

RESECTION OF THE ANKLE has suffered, in professional estimation, from essentially the causes that hindered the general acceptance of wrist resections. The number of bones, the complexity of synovial membranes, and the propinquity of many tendons, give many lurking places for disease, and often delay recovery, insure relapses, or destroy the functional value of the rescued foot. For these reasons many surgeons have preferred Syme's or Pirogoff's amputations. Better methods, however, have very much diminished this antagonism to resection. The results of limited operations are often excellent, and if extensive ones, sometimes leave a foot that is not much more than a stump, but it is, nevertheless, a much more useful stump than is usually obtained from amputation. Strictly speaking, resection of the ankle means removal of the articular surfaces of the tibia and astragalus, with or without the lower end of the fibula; usage, however, makes the phrase include more extensive invasion of the tarsus, at least as far as the mid-tarsal articulation. If both surfaces of the tibio-astragaloid articulation are removed, the resection is "complete." The operation was originally applied to the reduction of compound dislocations and fractures of the ankle, and, until about thirty years since, operations for injury considerably outnumber those for disease. Otis could find but three cases of resection for gunshot injury previous to 1861.

Results.—The death-rate from resection of the ankle for gunshot wounds in 45 cases, collected by Culbertson, was twenty-six per cent. Otis reports 33 cases from our own war, 7 only of which were technically complete, with a death-rate of twenty-nine per cent. He also collected 150 cases from other sources, nearly all more recent than our war, with a death-rate of 33.7 per cent. So far, therefore, the death-rate is higher than for ankle amputations, which in our war (Otis) was 25.1 per cent. The same authority concludes that the functional results are not very satisfactory, and prefers the "judicious use of the gouge and the bone-forceps" to formal exsections.

In civil practice the results for injury are better, the death-rate, according to Culbertson, for 152 cases being 12.5 per cent., and the functional results are better. Culbertson shows the death-rate for disease in 124 cases to have been but 8.06 per cent., which is not far from the mortality of Syme's operation done under similar circumstances. The death-rate of partial resections was but 6.55 per cent.

The operations made for injury usually result in anchylosis, and often with feet in faulty position, which greatly impairs their usefulness. Recurrence of disease in the tarsus is frequent when the operation has been done for caries. These reasons have led to the increased favor accorded to informal procedures.

Indications.—For gunshot injury, resection, in form, of the ankle-joint gives but indifferent results, and is in-

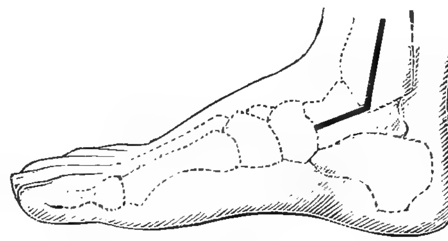

FIG. 3306.

dicated only under very favorable circumstances, and in cases which probably would do quite as well with informal removal of fragments and gouging.

Compound fractures or dislocations call for resection, generally partial or atypical, when the injury is attended with extensive damage to the soft parts, but not to nerves or vessels, or when the reduction of bones is difficult without the operation. Also, as a secondary operation, when suppuration has supervened upon a compound fracture and the tissues are already badly damaged, or cure is probable only through anchylosis, resection gives a speedier termination.

For caries, resection is rarely indicated in young children, and perhaps before puberty. In childhood, expectancy, with opening of abscesses, drainage, extraction of sequestra through sinuses, produces very satisfactory results. Even when, at this age, the caries is extensive, *évidement*, or its modification of scooping and setoning, as urged by Sayre, often saves the foot with nearly or quite perfect functions. After childhood, more formal operations come into question. The operation selected should be that involving the least mutilation of the soft parts consistent with complete extirpation of the disease. The retention of the malleoli, or of one only, gives a solidity to the parts which favors union in good position.

Methods.—The preference has been rather for lateral incisions, wholly or partly in the axis of the leg, as damaging the tendons less than transvere cuts. There have

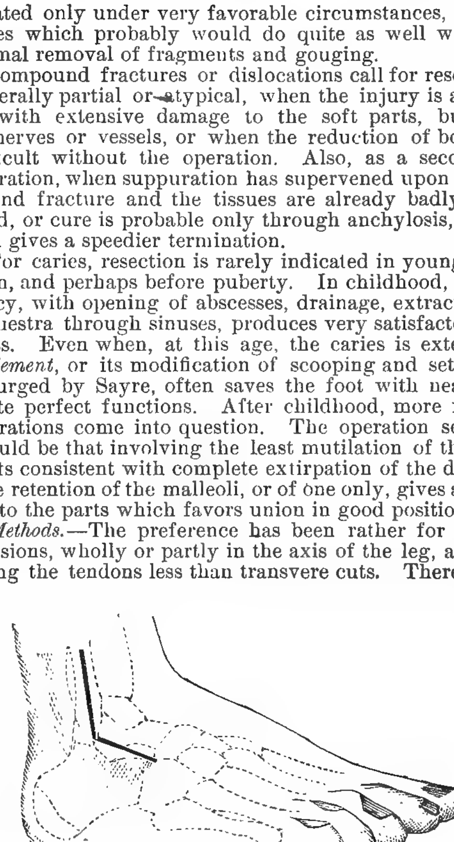

FIG. 3307.

been many varieties of this type. Figs. 3306 and 3307 show one of them, recommended by Wyeth,[58] which is made as follows: Commence an incision on the internal surface of

the tibia, about two inches above the tip of the inner malleolus, and carry it directly down to this point and thence forward from one inch to one inch and a half along the tarsus in the line of the metatarsal bone of the great toe (Fig. 3306). This incision extends a little anterior to the astragalo-scaphoid articulation. A light L-shaped incision is made upon the fibular side of the joint (Fig. 3307). With the Sayre periosteal elevator, lift from the diseased portions of bone the periosteum (with its attachments to the superjacent soft tissues undisturbed). Expose the outer malleolus and fibula as high as it is deemed necessary to remove this bone, and divide it with the exsector or chisel. As soon as the piece is removed, the joint is thoroughly exposed to view. Now, in the line of the tibial incision, further lift the periosteum of the tibia and tarsal bones, and, by forcibly bending the foot inward, dissect the tibia and inner malleolus outward through the wound on the fibular side. The diseased surfaces of the tibia and fibula may be sawn off with an ordinary saw, or with the exsector. The line of section should be at a right angle to the axis of the shafts of these bones, and should first remove the articular cartilage. Should the disease extend higher than this, an additional slice of bone may be removed, or any small sinuses thoroughly scraped out with Volkmann's spoon, and sponged out with sublimate, 1 to 1,000. The astragalus is now removed and the upper surface of the calcaneum sawn or chiselled off, so that a smooth and freshened surface is left. The cartilage should be scraped from the posterior articular face of the scaphoid. All of the soft tissues involved in the disease should be dissected away. The os calcis and tibia are now brought together, and if the sawn surfaces fit snugly with the foot at a right angle to the leg they are ready to be fastened. This is done by passing a nail or the Wyeth drill from the sole through the calcaneum up into the tibia. The drill is removed when sufficient firmness of the parts permits.

Langenbeck's subperiosteal operation also has bilateral incision. The external one consists of a cut about two and one-half inches long on the posterior border of the lower end of the fibula, and continues around the margin of the malleolus in a hook-shape. This is carried down to the bone, the fibula denuded without harm to the tendon of the peroneus longus. The fibula is divided at the upper level of the incision with the keyhole-saw, the fragment carefully separated from the interosseous ligament, which must be preserved on account of its influence on the reproduction of bone, and, finally, from its ligamentous attachments to the astragalus and calcaneum. If diseased, the articular surface of the astragalus is sawn off with a keyhole-saw from before backward. The internal incision is anchor-shaped, the curved part about an inch and one-half long, follows the lower border of the malleolus; the straight part, about two inches long, is vertical on the inner side of the tibia. Subperiosteal denudation as before. The tibia is sawn with keyhole or chain-saw, the remainder of its attachments carefully severed and the fragment removed, the detached piece of astragalus being removed afterward.

The great objection to the lateral incisions has been the imperfect exposure of the interior of the joint gained when they are used, which leads to the overlooking of points of disease and consequent relapses. Many operators, therefore, prefer the semi-lunar incision in some form, either anterior or lateral. Hancock[59] made an incision which beginning behind and about two inches above the external malleolus passed forward beneath that process across the front of the joint and terminated about two inches above and behind the inner malleolus. The cut divided skin only and the flap was dissected up, the peronei tendons detached from their grooves and drawn aside and the external lateral ligament cut. The fibula was cut off with bone nippers one inch and a half above its lower extremity. The foot was thrown over and the internal lateral ligament cut, the artery being saved and tendons of the tibialis anticus and flexor communis detached from their grooves. The foot was dislocated outward, the lower end of the tibia sawn off about a half-inch above the articulating surface and the astragalus removed.

Ashhurst[60] expresses his preference for "a semi-lunar incision, made to pass around the lower border of the outer malleolus, and then continued longitudinally in the line of the fibula." All tendons are saved except the peroneals, which are divided, the lower end of fibula removed, the astragalus wholly or partly removed. The foot is bent inward, the tibia cleared, its malleolus cut off with bone forceps, a short incision is made on the inner side of the limb, and the tibia sawn with a keyhole saw.

Kocher[61] makes an external semi-lunar incision from outside of the tendo-Achillis below the malleolus nearly to the extensors. The peroneal tendons being exposed, each is tied with a double ligature and cut between the ligature. The joint is freely opened, the foot bent inward, all disease searched for and removed. The divided tendons are reunited by a suture carrying a needle at both ends. Both needles are thrust into the upper segment a little distance apart, out at its cut end, into the cut end of the other segment and out upon the surface at different points the cut surfaces approximated and the suture tied. Kocher thinks that this gives a firmer suture than ordinary stitches.

Hueter[62] favored an anterior transverse cut with subsequent suture of tendons.

Vogt[63] has devised a somewhat novel method. He makes an incision just outside of the extensor tendons, beginning between the tibia or fibula above and running down to the junction of the calcaneum and cuboid. The fascia is divided, the tendons with their sheaths carefully detached from the parts beneath and drawn strongly inward. The extensor brevis is then cut and the outer lip of the wound drawn outward, and the capsule of the joint split open from top to bottom and with knife and elevator detached on both sides from the bone. The head and neck of the astragalus are then cleared and astragalo-scaphoid ligament cut through. Then a second incision is made from the first, beginning rather below the middle of the latter and running backward under the external malleolus. While the peroneal tendons are avoided the cut is carried down to the astragalus. The foot is separated, the ligament is cut away from the front of the malleolus and the interosseous ligament divided by a strong knife thrust into the aperture between the astragalus and os calcis. The foot being still supine the head of the astragalus is drawn outward with a strong hook, the fasciculus of the internal lateral ligament between the malleolus and the astragalus is cut; the latter bone is then drawn forward and its posterior connections cut and the bone removed. Through the cavity thus made all the adjoining bones can be readily examined and the extent of the subsequent resection,

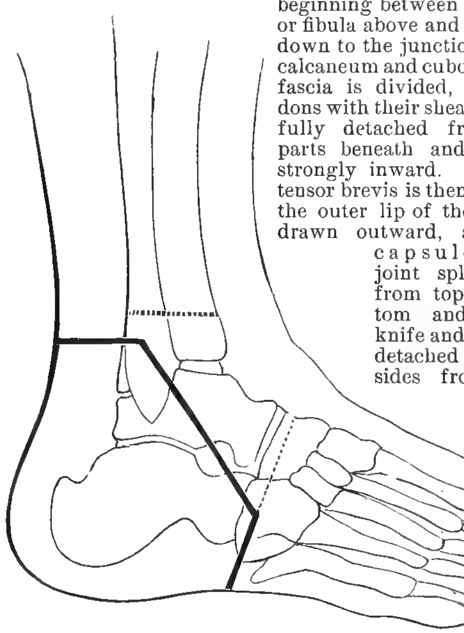

FIG. 3308.

whether with saw, gouge, or spoon depends upon the necessities of the case.

Mikulicz,[64] in 1880, performed what he styles an osteoplastic resection of the foot, which is intended for the relief of extensive disease of, or injury to, the posterior bones of the tarsus or of their covering tissues, and as a substitute for amputation at the ankle or in the leg. It seems[65] that the operation had been done in 1871 by Wladmiroff, but, the published account being in Russian, was overlooked until after Mikulicz had reinvented it. The operation is performed thus: The patient lies upon his stomach. An incision is carried from the tubercle of the scaphoid bone on the inside right across the sole to a finger's breadth behind the base of the fifth metatarsal bone. From each end of this incision others are carried upward and backward to the base of the malleolus of the same side. These again are joined by a cut across the back of the ankle dividing the tendo Achillis (Fig. 3308). All these cuts are carried to the bone. The flap is dissected from above, the joint opened from behind, the lateral ligaments cut, the astragalus and calcaneum are carefully dissected out and detached at the medio-tarsal joint. The malleoli and articular surface of the tibia and the posterior part of the cuboid and scaphoid bones are then sawn off, as shown by the dotted lines. The foot is brought back, the sawn surfaces adjusted, and the wound closed. Fig. 3309 shows the foot resulting in Mikulicz' case. Hopkins modified the operation by using bone pins to secure the parts together, by suturing the divided tendons, and attaching the tendo Achillis to the plantar fascia. The ends of the resected posterior tibial nerve were also sutured. This author has collected twenty-two cases of this operation; two died some months later of pulmonary tuberculosis, one having had a useful foot in the meantime; in one a subsequent resection of the rest of the tarsus was necessary, and in three subsequent amputation was performed. The remaining sixteen have useful extremities.

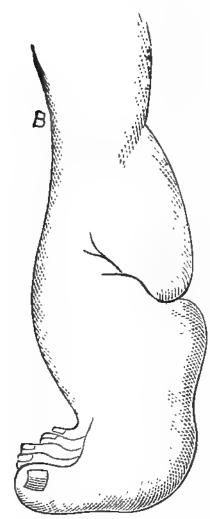

FIG. 3309.

The after-treatment of ankle-resection should be fixation in a good position with as few changes of dressing as practicable. The gypsum bandage or gypsum anterior splints with suspension-rod will suit as many cases as any one form of support. The suspension of the limb is a security against faulty position of the foot.

THE SMALL JOINTS of both the hand and the foot occasionally require excision for the same causes as the larger joints. The indications are those of resections in general under corresponding circumstances, due importance being given to the value of function saved in a finger-joint. For injury informal procedures are generally preferable.

The *phalangeal joints of the fingers* are generally removed through slightly curved lateral incisions, single or double, as necessary.

The *metacarpo-phalangeal joints* are best removed by dorsal straight incisions beside the extensor tendons, the latter being avoided by manipulation. The bone forceps is ordinarily used for section of the bones.

The corresponding *joints of the toes* are removed by the same method as those of the fingers. As the thumb is pre-eminently valuable to the hand, so the great toe is to the foot. In removing the metatarso-phalangeal joint of the great toe, the incision may be on the inside and semilunar in form. The operation has been recommended for hallux valgus, especially if complicated with painful bunion.

In both upper and lower extremity the resected parts should be kept separated by traction until the state of repair permits passive motion. The latter should be begun early, to preserve the function of the joints.

RESORCIN: RESORCINOL. Resorcin, chemically *Metadioxybenzene*, $C_6H_4(OH)_2$, is one of a trio of isomeric diatomic phenols, of which pyrocatechin and hydroquinone are the other two members.

Resorcin occurs in colorless crystals, having a peculiar smell, resembling that of carbolic acid, and a bitter-sweetish taste. Resorcin dissolves readily in water, and still more readily in alcohol and in ether. In its effects resorcin resembles its congener, carbolic acid, but is, in general, less active than that substance, and, in particular, very much indeed less poisonous, constitutionally. Resorcin inhibits bacterial growth, but probably less potently than carbolic acid. Locally the drug is without effect upon the sound skin, but applied, undiluted, to a moist mucous

membrane, it is mildly caustic, while at the same time anæsthetic and healing. By reason of the anæsthesia it produces, resorcin may be applied even to such sensitive parts as the mucous membrane of the larynx (Andeer). Internally, resorcin may be given in very considerable doses, as compared with carbolic acid, and such doses, administered to a fevered subject, will show to a marked degree the peculiar antipyretic effect so characteristic of the phenols. After a dosage of from 2.00 to 3.00 Gm. (from thirty to forty five grains) there set in, in a few minutes, quickening of heart-action and of breathing, reddening of the face, and buzzing in the ears, with giddiness. Within fifteen minutes sweating begins, speedily becoming active, whereupon the antecedent derangements abate, and at the same time the pyrexial temperature rapidly falls—so rapidly as perhaps to reach the normal point within an hour. The sweating does not last long, so that after the lapse of an hour from the time of dosing, the fever-patient may have a naturally moist skin only, with temperature and pulse-rate reduced to the normal. But while defervescence by resorcin is quick to occur, it is also quick to give way to the natural tendency of the fever to regain its former height. Within from two to four hours, therefore, the temperature often begins its succeeding rise, and within a single additional hour may have attained its original height. Such rapid after-risings of temperature may be attended by a chill. Resorcin is variable in its action; sometimes the fall of temperature is slight, and sometimes the by-effects are excessive and even alarming. Thus, after medicinal doses, there have been observed delirium and illusions, with muttering speech and convulsive trembling of the hands, and, in one case at least, a deep comatose sleep. In overdosage resorcin is competent to induce constitutional poisoning after the general type of poisoning by the phenols—giddiness, insensibility, profuse sweating, great reduction of temperature and general collapse, with olive-green coloration of the urine, being the prominent symptoms. Such alarming condition has followed a succession of doses increased from half a drachm to two drachms. Therapeutically, resorcin is used for both local and constitutional medication. Locally, resorcin is possible for a simple "antiseptic" effect, but is surpassed in this therapeusis by so many other agents as to be little used for the purpose. But for a combined antizymotic and *healing* effect the local application of resorcin may be quite serviceable. Thus injections of a five per cent. aqueous solution have been made into the bladder, in cystitis, and into suppurating cavities, with good effect, and salves of resorcin have abated malignant and syphilitic ulcerations. Internally resorcin has been used for its antipyretic action, in which application the medicine presents the feature of a fair degree of safety and efficiency combined; but the action is evanescent and attended by disagreeable excitement and sweating. The dose of resorcin for an antipyretic effect ranges from 2.00 to 4.00 Gm. (from thirty to forty-five grains), best given in divided doses and administered, dry, in a wafer or capsule, or in solution in water, sweetened and aromatized. Constitutional effects are also asserted (Andeer) to be procurable, in diseases attended by an affection of the skin, by inunction of resorcin in admixture with vaseline, in proportion of from five to eighty per cent., such effects being the abatement of symptoms in so-called zymotic diseases. Andeer claims to have thus produced striking amelioration in such diseases as small-pox, scarlet fever, measles, and leprosy, by inunctions, over the whole body, of resorcin-vaseline. *Edward Curtis.*

RESPIRATION, PHYSIOLOGY OF (Gr., ἀναπνοή, ἀνάπνευσις; Lat., respiratio; Fr., respiration; It., respirazione; Ger., Athmung). There are three distinct conceptions of respiration in medical and popular literature, representing three stages in the progress of knowledge concerning this subject: (1) That it consists of the mechanical process of supplying the lungs with air, gills with water, etc. (see below, under Mechanics of Respiration); (2) that it is the change taking place in the blood during its passage through a respiratory organ (lung or gill) (see below, under External Respiration); (3) the conception held at the present day, that it is the taking up of oxygen and the giving off of carbon dioxide by living matter; or, in other words, it is that part of the nutrient process which has to do with nutriment and waste in the gaseous form, and that the mechanical movements for supplying air or water, and the changes occurring in a respiratory blood, are only accessories of the essential process, and are sometimes absent.

Respiratory Media.—These are the sources from which oxygen is obtained for respiration, and into which carbon dioxide is excreted. They are air, and water containing oxygen in solution. If an animal breathes in the air, its respiration is said to be *aërial*; if in water, *aquatic*. In some cases—in tadpoles, for example—both media are used at the same time.*†

Direct and Indirect Respiration.—In organisms of minute size, like the *amœba*, the living substance is all so near the oxygen in the surrounding medium (water) that oxygen is taken directly from the water, and carbon dioxide is given off directly to it (Fig. 3310). In animals of larger size, especially those of complex organization, if the respiratory medium simply bathed the surface of the body, most of the living matter would be too far from the oxygen supply to enable the organism to carry on its functions with the highest efficiency; hence there are present special respiratory organs to facilitate the furnishing of oxygen to the tissues, and the removal of carbon dioxide from them.

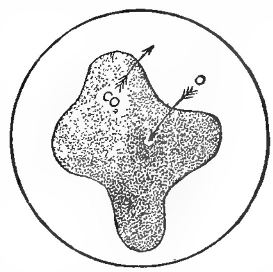

FIG. 3310.—Diagram of an Amœba, Illustrating the Direct Respiration of Minute Aquatic Animals, in which the living substance takes oxygen directly from the surrounding medium, and returns carbon dioxide directly to it, no respiratory organs being present. O, oxygen; CO_2, carbon dioxide.

In the larger *protozoa*, as the *infusoria*, cilia are present on the surface, which, by their motion, produce currents in the water, or change the position of the animal, in either case insuring fresh supplies of the respiratory medium. Water is also taken into the body, thus bringing the oxygen into intimate contact with the living substance farthest from the surface.

In the *metazoa* the size of the body is often considerable, and more elaborate means are employed to bring

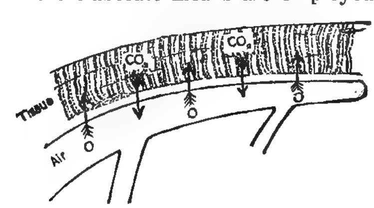

FIG. 3311.—Diagram Illustrating the Direct Respiration of Insects, in which Air is conveyed to the Tissues through Tubes (tracheæ). The tissues take oxygen directly from the air, and return carbon dioxide directly to it, no respiratory blood being present. O, oxygen; CO_2, carbon dioxide. As indicated by the arrows pointing in the two directions, the tissues take more oxygen from the air than they give off carbon dioxide to it. Air, the air in the trachea. Tissue, all the tissues of the insect's body are here represented by a piece of striated muscular fibre.

the respiratory medium in proximity to the living substance. In some of them—the *sponges*, for example—there are water canals in all parts of the body, through which streams of water constantly flow, thus bringing

* In the forms of bacteria known as *anærobic*, *i.e.*, living in situations devoid of free oxygen, the oxygen needed for respiration is, according to Bernard,[1], [2], obtained by breaking up some of the compounds in the surrounding medium.

† When an animal, like a tadpole, employs both air and water as respiratory media at the same time, the carbon dioxide seems to be principally excreted into the water, and the oxygen mainly derived from the air (Science, vol. vii., p. 394, 1886).

the oxygen in contact with the tissues, and removing carbon dioxide from them. In still higher forms—*insects*, etc.—there is a complex system of tubes, called *tracheæ*, extending from the exterior to every organ and tissue, and serving to conduct air to and from every part. The living substance can thus take oxygen directly from the air in the tubes, and return carbon dioxide directly to it, [4,9] (Fig. 3311). It will be seen from the above that what may be properly designated *direct respiration*—that is, taking oxygen directly from the respiratory medium by the tissues, and returning carbon dioxide directly to it by them—is found in both aërial and aquatic animals.

In man and the other vertebrates, also in many invertebrates, this direct respiration is not found, but there is a circulating liquid—*respiratory blood*—containing hæmoglobin or its equivalent, which serves as a carrier of oxygen from the respiratory medium to the tissues, and of carbon dioxide from them back to the respiratory medium in return. There are also present special respiratory organs (*gills* for aquatic and *lungs* for aërial respiration). To make the respiratory organs efficient, there is a complex nervous, muscular, and bony or cartilaginous mechanism for constantly supplying the respiratory organs with fresh air or water, and constantly removing that which has become vitiated. Finally, there is present a complex vascular mechanism for the circulation of the blood.

The form of respiration just described is called *indirect respiration*, for the reason that the tissues do not get the

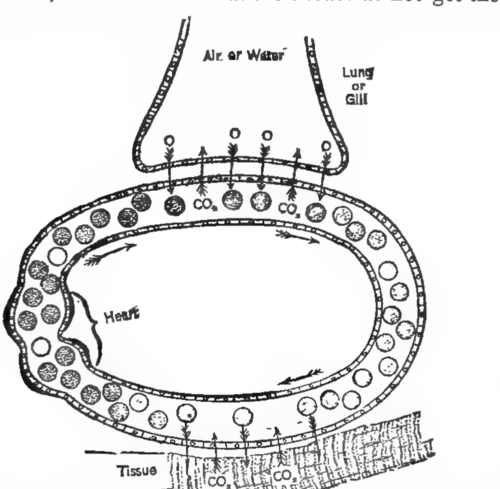

FIG. 3312.—Diagram Illustrating Indirect Respiration by Means of Respiratory Organs and a Respiratory Blood. Air or Water, the respiratory medium bathing the respiratory membrane and supplying the blood with oxygen and removing carbon dioxide from it. Lung or Gill, the respiratory membrane. Heart, the central and motor part of the circulatory system. This system, except at the heart, is represented only by the endothelial lining common to the entire system. The arrows extending along the vessels indicate the direction of the blood-current. O, oxygen; CO_2, carbon dioxide. As indicated by the arrows pointing in the two directions, more oxygen is taken up by the blood and the tissues than there is carbon dioxide given off in return. The diagram also indicates that the carbon dioxide is mainly in the plasma, and the oxygen in the red blood-corpuscles. The presence of the oxygen in the corpuscles gives the blood a lighter color, as indicated by the shading of the corpuscles; as also indicated by the shading of the corpuscles, the arterial blood is not fully saturated with oxygen, nor is the venous blood entirely devoid of it. Tissue, all the tissues of the body are here represented by a piece of striated muscular fibre.

oxygen directly from the air or water, but indirectly through the respiratory blood [1] (Fig. 3312).

RESPIRATORY ORGANS.—In man and the other animals in which a respiratory blood is present, and the respiration is consequently indirect, the respiratory organs consist essentially of a thin expanded membrane, *the respiratory membrane*, [15] bathed on one side by the respiratory medium, and on the other by the respiratory blood, which is spread out in a thin, almost continuous sheet in the capillaries. This respiratory membrane, in man and the mammals generally, is in the form of two great elastic sacs called lungs, in which the surface is repeatedly folded, thus forming an almost infinite number of secondary sacs—the *pulmonary alveoli, vesicles, air-sacs*, or *air cells* (Figs. 3313 and 3317). The lungs are placed in the

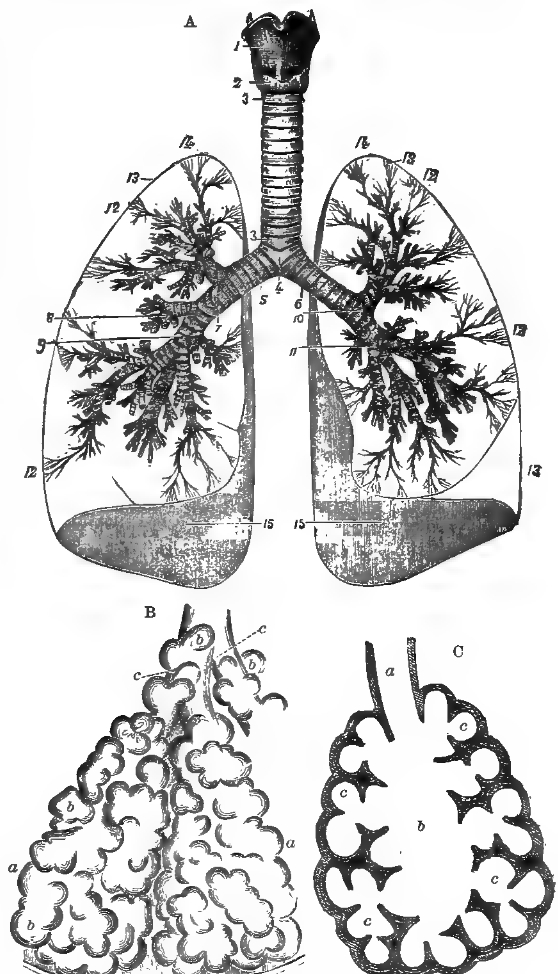

FIG. 3313.—The Trachea, Bronchi, and Ultimate Termination of the Bronchi in the Lungs. (A) Ventral view of the larynx, trachea, and bronchi, and of the lungs in outline and opened so as to show the tree-like branching of the bronchi (Sappey). 1–2, the larynx; 3–3, the trachea; 4, bifurcation of the trachea to form 5 the right, and 6 the left bronchus; 7, division extending to the cephalic or superior, 8 to the middle, and 9 to the caudal or inferior lobe of the right lung; 10, bronchial division to the cephalic or superior lobe, and 11 to the caudal or inferior lobe of the left lung; 12, ultimate ramification of the bronchi; 13, contour of the lungs; 14, summit; and 15, base of the lungs. (B) Two lobules from the lung of a new-born child, half diagrammatic and magnified twenty-five diameters (Kölliker). Three ultimate bronchial tubes or lobular bronchioles are shown, but the terminal lobule is shown on but two of them. *a,a*, Lobules; *b,b*, alveoli or air-vesicles; *c,c*, terminal bronchial tubes or lobular bronchioles. (C) A single lobule in section, magnified (Dalton). *a*, Terminal bronchial tube opening into *b*, the alveolar or lobular passage; *c,c,c,c*, air-vesicles or alveoli. The pulmonary capillaries ramify in the shaded partitions between the alveoli.

air-tight chest or thorax, and communicate with the exterior through the respiratory or air-passages (Fig. 3315). In shape the lungs conform accurately to the cavity left in the thorax by the heart and great vessels; that is, the costal surface of each lung is convex, while the mesal surface is somewhat concave where it is moulded to the surface of the heart. At the base the lungs rest upon the diaphragm, and from their elasticity follow all its varying shapes (Fig. 3319). At the apex the lungs are

bluntly pointed, fitting the corresponding cavity in the cephalic or upper part of the thorax.

In man the right lung is divided into three somewhat unequal lobes by two fissures extending from the costal

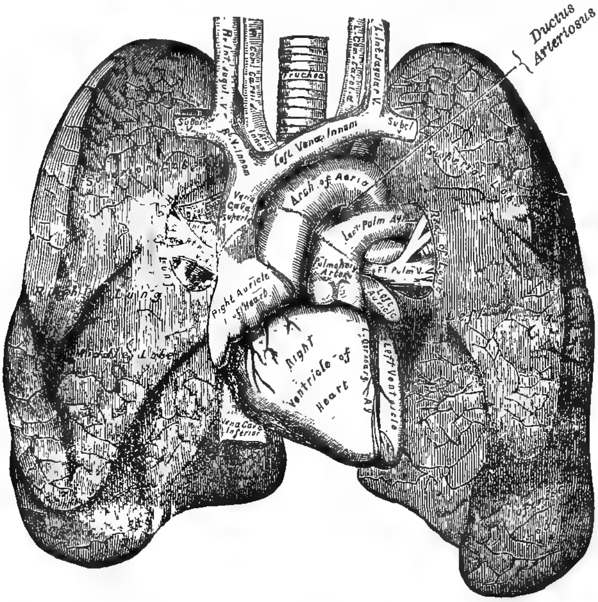

Fig. 3314.—Ventral View of the Lungs, Trachea, Heart, and Great Vessels. (Gray.) The lungs are slightly inflated, and separated so as to bring into better view the heart, etc. The right lung is divided by two fissures into three lobes, and the left one by a single fissure into two lobes.

surface toward the root of the lung. The left lung is divided into two lobes by a single fissure (Fig. 3314). The so-called root of the lung is at the point of suspension of the lung, and each is composed of a bronchus, the pulmonary blood-vessels, lymphatics, and nerves, and the connective tissue binding these structures together (Figs. 3313 and 3314). Each lung is covered by a serous membrane, a reflection of the corresponding pleura, which, commencing at the root, is reflected over the entire surface, entering the fissures and forming a complete envelope for the lung. The connective-tissue layer of the pleura covering the lungs is directly continuous with their connective-tissue framework, so that the pulmonary pleura forms an essential part of the lung-structure.

The *Respiratory* or *Air-passages* are tubes or openings serving to conduct the air to and from the lungs. They are the two nasal passages, sometimes also the mouth, the pharynx, which like the mouth is also common to the alimentary canal, the larynx, trachea, and bronchi (Figs. 3313 and 3314). The bronchi continually divide, like the branches of a tree, without anastomosing, and finally terminate in sac-like enlargements which are the true respiratory parts of the lungs (Figs. 3313 and 3317). From this arrangement of the true respiratory parts of the lung at the ends of the bronchi the lung is sometimes not considered as composed of a great sac, as stated above, with foldings of the surface and a minute bronchial twig connected with each minute fold, but it is supposed to consist of a great number of small, independent sacs closely bound together. On this view, the comparison with a tree, especially one with divided leaves, might be continued, each leaf representing an ultimate lobule of the lung (Figs. 3313 and 3317).

The air-passages of the lungs, and the respiratory passages in the nose, are lined with ciliated epithelium. In each case the motion of the cilia produces a current toward the pharynx. This current carries dust and mucus into the pharynx, from which they are readily expelled. (See also articles on the Bronchi, vol. i., and the Minute Anatomy of the Lung, vol. iv.)

Vascular and Nervous Supply of the Lungs.—The blood going to the lungs is of two kinds and from two sources: (1) The impure or venous blood from the right side of the heart going through the pulmonary artery to the lungs to be purified or arterialized; and (2) pure or arterial blood from the left side of the heart going through the bronchial arteries to the lungs for the nourishment of their substance. The first, after purification, is returned to the left side of the heart by the pulmonary veins. The second, after serving for the nourishment of the lung-tissue, is returned in part through the bronchial veins to the right side of the heart, and in part through the pulmonary veins to the left side of the heart; in other words, part of the arterial blood of the bronchial arteries is returned as arterial blood directly to the left side of the heart from which it was sent, without first passing in the regular way into the systemic veins and the right side of the heart [6, 7]. "In their course together through the lung the artery is usually found above and behind the bronchial tube, and the vein below and in front." [7] The bronchial arteries and their branches ramify in the lung-tissue without such definite relations to the bronchi as with the pulmonary vessels.

The nerves of the lungs are derived from the vagus and the sympathetic, and form a dense plexus on the dorsal and another on the ventral side of the root of each lung (the so-called anterior and posterior pulmonary plexuses). From these plexuses the nerves ramify in the substance of the lung, following the bronchi.

External Respiration.—Under this heading are included the changes which occur in the respiratory blood during its passage through the lungs or gills, and also the changes occurring simultaneously in the respiratory medium.

According to the view of chemists and physicists, the earth's atmosphere, or the air, as it is more commonly called, is a mechanical mixture composed princi-

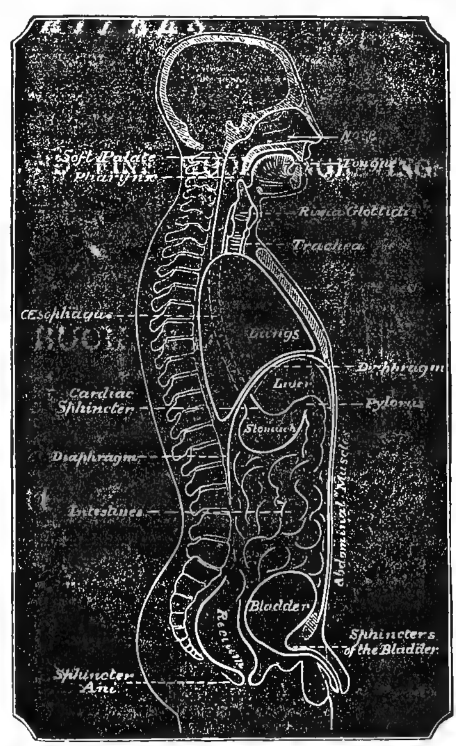

Fig. 3315.—Diagrammatic Section of the Body. (Kirkes.)

pally of oxygen and nitrogen, with a minute quantity of carbon dioxide and a varying amount of watery vapor.

The composition of the air from various parts of the earth's surface has been found nearly uniform. When dried and reduced to the standard temperature and pressure (a temperature of zero centigrade and a pressure of 760 mm. of mercury), the composition is about as follows: *

Oxygen	20.81 per cent.
Nitrogen	79.15 " "
Carbon dioxide	0.04 " "
	100.00 per cent.

Air coming from the lungs (*expired air* or *breath*) of man, or one of the other warm-blooded animals, compared with the inspired or atmospheric air, shows the following changes, due to its sojourn in the lungs: (1) A marked decrease in the amount of oxygen; (2) a great increase in the quantity of carbon dioxide; (3) slight if any change in the amount of nitrogen; (4) usually an increase in the quantity of watery vapor; (5) the temperature is closely approximated to that of the body, being usually warmer than the surrounding air; (6) traces of organic matter have been added; (7) traces of ammonia are often present, and sometimes odors from substances taken into the stomach, as alcohol, garlic, etc.

The surrounding air is usually at a lower temperature than the body, and is therefore heated by the body when taken into the lungs. In this case it increases in volume, following the law for the expansion of gases by heat. If the temperature of the air is higher than the body, it is cooled by being inspired and diminishes in volume, following the same law. But after making allowance for changes in temperature and in the amount of aqueous vapor present, the expired air is usually slightly less in volume than the inspired air, due to the fact that the volume of oxygen absorbed from it is greater than that of the carbon dioxide added to it. This diminution is variously estimated from 1 to 2.5 per cent. of the original volume inspired.

Owing to the change in volume, a comparison of the percentage composition of inspired and expired air does not furnish exact information concerning the quantitative changes which the air undergoes in the lungs. These changes can only be determined accurately by comparing the absolute amount of the various constituents of a known volume of inspired air with the absolute amount of the various constituents of the same air after it is expired.[8] †

Gases of the Blood.—It was thought by Lavoisier,[9] and those who followed his teachings, that carbon dioxide was formed in the lungs by an oxidation of the waste materials brought to the lungs by the blood. This view was found untenable by later investigators, who proved that the arterial blood was cooler than the venous. This could not be the case if oxidation sufficient to produce all the carbon dioxide appearing in the expired air took place in the lungs. It was also shown that, in blood from any part of the body, carbon dioxide and oxygen could be obtained directly without chemical means; and that more carbon dioxide could be obtained from venous than from arterial, and more oxygen from arterial than from venous, blood. At the present day it is known that the respiratory process occurring in the lungs is an absorption of oxygen from the air by the blood, and a return to the air of carbon dioxide already existing in the blood.

The exact office of the blood in respiration could only be determined by discovering the nature and relations of the gases of arterial and venous blood.[20] *

From one hundred volumes of blood about sixty volumes of gas may be extracted. This does not diminish the volume of the blood. The gas is composed of oxygen, nitrogen, and carbon dioxide, the proportions of these gases varying in the different kinds of blood.

In order that the results shall be of the greatest value, the two kinds of blood from which the gases are extracted should be from the same animal, under similar conditions. According to five such double analyses of dog's blood by Schoeffer,[8] the following averages were obtained from 100 c.c. of blood:

Arterial Blood: Oxygen, 19.2 c.c.; nitrogen, 2.7 c.c., carbon dioxide, 39.5 c.c.

Venous Blood: Oxygen, 11.9 c.c.; nitrogen, 1.7 c.c.; carbon dioxide, 45.3 c.c.

This table shows that in 100 c.c. of arterial blood there are 7.3 c.c. more oxygen, and 5.8 c.c. less carbon dioxide than in the same volume of venous blood. From numerous determinations made by other observers, Zuntz gives as an average, an increase of 8.15 per cent. of oxygen and a decrease of 9.2 per cent. of carbon dioxide in 100 c.c. of arterial blood as compared with the same volume of venous blood. According to the very numerous (nearly two hundred) determinations of the gases of arterial blood of the dog by Bert and Pflüger, the gases in 100 c.c. of blood are as follows:[8] Oxygen, 18 to 20 c.c.; nitrogen, 1 to 2 c.c.; carbon dioxide, 38 to 40 c.c. In human arterial blood the gases were found by Setschenow[8] in the following quantities in a single determination: Oxygen, 21.6 c.c.; nitrogen, 1.6 c.c.; carbon dioxide, 40.3. So far as this single determination goes, the gases in human blood agree very closely in quantity with those found in dog's blood, and any conclusions drawn from observations on the gases of dog's blood might probably be legitimately applied to human blood.

Arterial blood is of nearly uniform composition throughout the entire body, containing a slightly less percentage of oxygen in the smaller arteries farthest from the heart, due to the diminished number of blood-corpuscles as shown by the lower specific gravity,[8] and in part, probably, also to the true respiration occurring in the blood itself. The venous blood differs considerably in composition in different parts of the body, hence that for the extraction of the blood-gases should be taken from the right heart or the pulmonary artery, where it is mixed, if a general average is sought. A comparison of the gases of arterial and venous blood from any part of the body shows, however, wherein lies the difference between them so far as respiration is concerned, and it is found to be a difference only in the proportions in which oxygen and carbon dioxide are present in the two kinds of blood. Arterial blood may, therefore, be defined as blood containing a relatively large percentage of oxygen (eighteen to twenty per cent.), and a relatively small percentage of carbon dioxide (thirty-eight to forty per cent.).

Venous blood may be defined as blood containing about eight per cent. less oxygen and six to eight per cent. more carbon dioxide than is present in arterial blood. In ordinary respiration the blood is not saturated with either of the respiratory gases, as is shown by shaking blood

* While it was formerly supposed that the composition of the atmosphere in a given place was constant, later investigations have shown that there is considerable variation; the oxygen has been found to vary from 20.45 to 21.01 per cent., and the carbon dioxide from 0.0206 to 0.0417 per cent.[8]

† It is apparently assumed by many writers on respiration that, if the percentage composition of inspired air and that of expired air are compared, one can determine accurately the changes occurring in the air during its sojourn in the lungs, thus neglecting the diminution in volume. For example, in the excellent works of Wundt (Physiologie des Menschen, 4th ed., p. 388), and Foster (Text-book of Physiology, 3d ed., p. 341), percentage compositions of inspired and expired air are given with the statement that, when dried and compared at the standard temperature and pressure, the expired air is $^1/_{50}$th to $^1/_{40}$th less in volume than the same air when inspired.

Inspired air: Oxygen, 20.81 per cent.; nitrogen, 79.15 per cent.; carbon dioxide, 0.04 per cent.

Expired air: Oxygen, 16.033 per cent.; nitrogen, 79.557 per cent.; carbon dioxide, 4.38 per cent.

The loss in oxygen by the air, and its gain in carbon dioxide, are both determined by comparing the percentage differences, without apparently taking any account of the diminution of volume. It is further stated by Dr. Foster, with reference to the nitrogen: "The quantity of nitrogen in the expired air is sometimes found to be greater, as in the table, but sometimes less, than that of inspired air." While it is true that the *percentage* quantity of nitrogen in the expired air is greater, as shown in the table, the absolute amount is less, provided there is the diminution in volume described. Taking the least diminution mentioned, $^1/_{50}$th or 2 per cent., then 100 c.c. of inspired air would measure but 98 c.c. when expired. If, now, 79.557 per cent. of this is nitrogen, the total nitrogen in the 98 c.c. of expired air would be $(98 \times 79.557) = 77.96586$ c.c.; and as in the 100 c.c. of air originally inspired there were 79.15 c.c. of nitrogen, there has been an actual diminution of $(79.15 - 77.96586) = 1.18414$ c.c. of nitrogen, instead of an increase as stated by Dr. Foster.

* The terms *arterial* and *venous blood* are unfortunately used in two senses, viz., in a morphological sense, relating to the kind of blood-vessel containing the blood without regard to its quality, and in a physiological sense, referring solely to its quality without regard to the vessel containing it. The terms are used only in the latter sense in the present article.

with them. If shaken with pure oxygen or with air, blood will take up about twenty-three per cent. of its volume of oxygen, instead of twenty per cent. as in ordinary respiration, and if it is shaken with pure carbon dioxide the blood will absorb about its own volume of that gas.[10]

Relations of the Gases in the Blood.—It is believed that but a small amount is in simple solution, but that the greater part is in loose chemical combination. This is supported by the fact that when blood is put under the mercurial pump (Fig. 3316), a small amount of gas is gradually given off, following the Henry-Dalton law for the absorption of gases by liquids; but the larger part of the gas comes off only when the pressure falls to about twenty millimetres of mercury; then it is suddenly given off.

The oxygen simply dissolved in the blood plasma has been found to exceed but little the amount that water dissolves at the same temperature. It has been proved conclusively that the main part of the oxygen in the blood is combined with the hæmoglobin in the red blood-corpuscles (see also article Blood, vol. i.). The relations of the carbon dioxide are not quite so simple, for although the blood contains less carbon dioxide than would be absorbed by water at the same temperature, it does not follow the law for the absorption of gases by liquids; and it is the prevailing belief among physiologists that it is all chemically combined in the plasma of the blood, very little being in the corpuscles.[6] As part of the carbon dioxide is readily removed from the blood by the mercurial pump, it is called the "loose" carbon dioxide, and is supposed to be united with the soda of the blood in the form of a bicarbonate; while the part ("fixed" carbon dioxide) which cannot be pumped from the blood serum without first adding an acid, is supposed to be united to the soda in the form of a carbonate. It has been found by experiment that in removing the blood-gases the hæmoglobin acts like an acid, enabling all the carbon dioxide to be pumped out without adding an acid. If the red corpuscles containing the hæmoglobin are first removed, only the "loose" carbon dioxide can be obtained, as stated above, unless an acid is first added.[8] The nitrogen in the blood seems to be in simple solution.

Color of the Blood.—It has been found that hæmoglobin containing oxygen (*oxyhæmoglobin*) is of a bright scarlet color, *i.e.*, the color of arterial blood, while hæmoglobin not containing oxygen (*reduced hæmoglobin*) is of a darker color, that is, the color of venous blood (Fig. 3312). This is true of the hæmoglobin in the blood, whether it is in the blood-corpuscles or dissolved in the plasma, and it is entirely independent of the carbon dioxide that may be present. This is shown by the blood of animals dying of carbon dioxide poisoning in a confined atmosphere of pure oxygen, [9,11]. Under ordinary circumstances, however, the color of the blood is a good test for determining its respiratory quality, as carbon dioxide escapes at the same time that oxygen is absorbed. But it is truly arterial only when its hæmoglobin is nearly saturated with oxygen and the plasma contains a moderate amount of carbon dioxide (see above).

Gas-interchange in the Lungs.—When the venous blood reaches the lungs it is spread out in a thin sheet in the pulmonary capillaries and separated from the air on two sides, in many places only by the epithelium of the capillaries and that lining the alveoli of the lungs (Fig. 3317). The blood being thus practically in contact with the air, oxygen passes through the membrane separating the air from the blood into the blood, in accordance with the law for the absorption of gases by liquids; but as soon as it reaches the blood-plasma, the reduced hæmoglobin combines chemically with it to produce oxy-

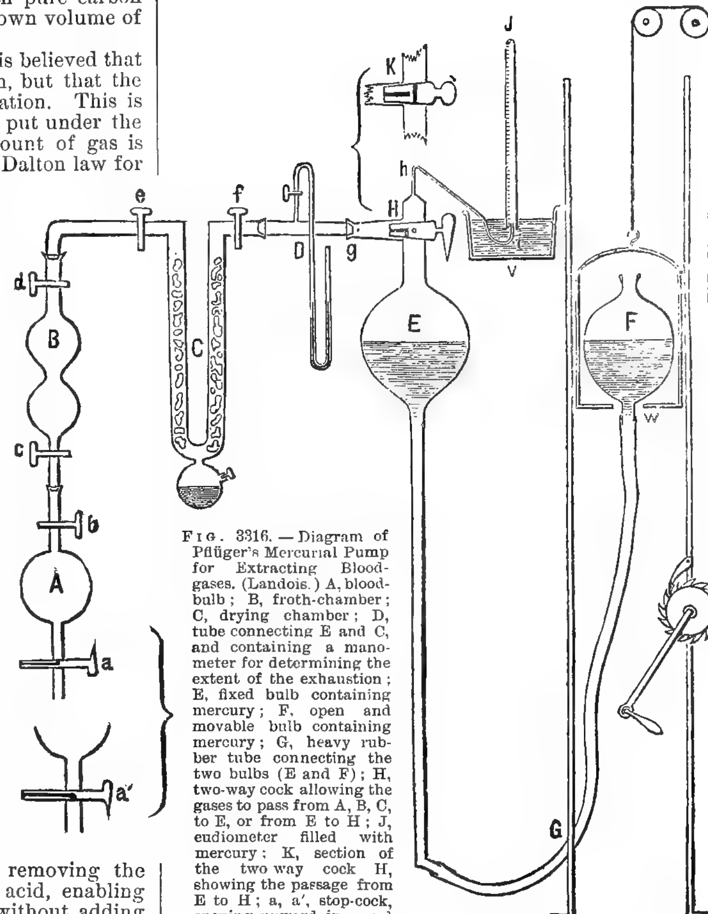

FIG. 3316.—Diagram of Pflüger's Mercurial Pump for Extracting Blood-gases. (Landois.) A, blood-bulb; B, froth-chamber; C, drying chamber; D, tube connecting E and C, and containing a manometer for determining the extent of the exhaustion; E, fixed bulb containing mercury; F, open and movable bulb containing mercury; G, heavy rubber tube connecting the two bulbs (E and F); H, two-way cock allowing the gases to pass from A, B, C, to E, or from E to H; J, eudiometer filled with mercury; K, section of the two way cock H, showing the passage from E to H; a, a′, stop-cock, opening upward in a, and downward in a′; b, c, d, e, f, stop-cocks; g, connection between the collecting and drying part of the apparatus and the pump; h, glass tube connecting the bulb E with the eudiometer J: i, mercury into which the eudiometer and the tube h dip; v, dish of mercury (pneumatic trough); w, support in which the bulb F is raised and lowered by the ratchet-wheel shown at the right. The following directions for the use of this pump are taken from Landois: The blood-bulb A is first exhausted by means of a mercurial pump, and then carefully weighed. The end of the stop-cock a is tied into a blood-vessel and the cock turned so that the blood flows into the blood-bulb. When a sufficient amount of blood is collected the cock is turned in the position (a′), and after cleaning the outside of the blood-bulb it is again carefully weighed to ascertain the amount of blood that has been collected. The froth-chamber (B), as its name implies, is to catch the froth formed during the energetic evolution of the blood-gases. It is connected with the other parts of the apparatus, on both sides, by means of stop-cocks. The drying chamber C is composed of a U-tube filled with pumice stone saturated with sulphuric acid, and at the base of the U-tube is a bulb partly filled with sulphuric acid. The blood-gases in traversing this chamber are completely dried. In working the pump, the whole apparatus is emptied of air by filling the bulb E with mercury, by raising the bulb F, after turning the cock H in the position K, so that the air in E can pass out through the tube h, which is not yet dipped into the mercury, and then turning the cock H so that it will connect with the rest of the apparatus. All the other cocks except a and b are opened, and the bulb F is lowered until part of the air is exhausted, then the cock H is turned to the position of K and the air is got rid of by raising F. This process is repeated until the manometer in D shows a complete vacuum. Then the cock H is turned to the position K, and the bulb F raised until mercury runs out of the tube h, when the cock is turned to the position H, and the tube h is placed in the pneumatic trough v, under the eudiometer J. A vessel of water at about 60° C. is now raised so as to immerse the blood-bulb, and the cocks, except a, are opened and the bulb F lowered. After part of the gas has passed over to E, the cock H is turned to the position K, and the gas is forced over through the tube h into the eudiometer J. This process is repeated until, as shown by the manometer in D, the gases are all extracted.

hæmoglobin, leaving the plasma as poor in oxygen as before. The absorption of oxygen by the plasma there-

fore continues until all the reduced hæmoglobin is oxidized and changed to oxyhæmoglobin, and the plasma is saturated with oxygen at the temperature of the blood and the partial pressure or tension of the oxygen in the alveolar air.*

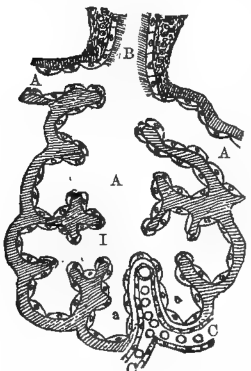

FIG. 3317.—Diagram of Part of a Pulmonary Lobule, to Show the Relations of the Various Parts, especially the Blood Capillaries and the Alveoli. A, A, A, Alveolar or lobular passages; a. a, pulmonary alveoli, air-vesicles, or air-cells. These open either into the alveolar passages singly or in groups; B, ultimate bronchial tube or lobular bronchiole. It is lined with ciliated epithelium and opens into the alveolar passages on one side and joins other bronchioles on the other; C, C, capillary containing blood-corpuscles. The capillary is exposed to the air on two sides, being separated from the air only by the epithelium lining the alveoli. In the actual specimen all the partitions are filled with capillaries; I, opening into the alveolar passage of an infundibulum or group of alveoli.

This explains why the oxygen needed for respiration is obtained by the blood independently of the partial pressure or tension of the oxygen in the air, provided the tension does not fall too near the point of dissociation of oxyhæmoglobin; for, according to the law of absorption of gases by liquids, a certain amount of oxygen enters the plasma of the blood whether there is a greater or less amount of oxygen in the air than normal. The reduced hæmoglobin combines with the oxygen to produce oxyhæmoglobin independently of the tension of the oxygen. If the air is very rich in oxygen, the hæmoglobin of the blood is quickly changed to oxyhæmoglobin, for a sufficient amount is rapidly absorbed by the plasma and thus brought into combining distance of the hæmoglobin. If, on the other hand, the tension or partial pressure of the oxygen in the alveolar air is small, the hæmoglobin will still combine with the same amount, but it will take a longer time, from the slowness with which the oxygen is absorbed and brought into combining distance by the plasma.

At the same time that the oxygen is passing from the alveolar air into the blood, carbon dioxide is passing from the blood to the air; hence the designation of the process as an *exchange of gases.* The same principles are supposed to govern the exit of carbon dioxide as for the absorption of oxygen—the air in the alveoli of the lungs contains carbon dioxide at a less tension than it possesses in the blood, so that the excess of carbon dioxide tends to pass from the blood to the air to establish equilibrium. The case is not so simple as this, however, for, as the entire amount of carbon dioxide in the blood is in combination, it could not be expected to follow the laws of diffusion determined by difference of tension. If it is in true chemical combination it has no tension in the blood. The explanation has been sought in the fact that oxyhæmoglobin acts as an acid in setting free the carbon dioxide, and this action seems to be all the more energetic at the moment when the oxygen is taken up to form the oxyhæmoglobin. The pulmonary epithelium covering the alveoli (Fig. 3317) is also supposed to assist by actively excreting carbon dioxide. Finally, as the amount of carbon dioxide in venous blood may be represented by a tension of 41 mm. hg., and the partial pressure or tension of the air in the pulmonary alveoli is only 27 mm. hg.,[6] it is supposed that this difference in tension is sufficient, with the assistance of the acid-like action of the oxyhæmoglobin, to dissociate the combined carbon dioxide, when it would be subjected to the laws of absorption of gases, and would escape to the air of the alveoli, where the carbon dioxide tension is lower. Certain it is that this transfer is constantly taking place. Equilibrium would, however, soon be established between the gases of the blood and the alveolar air if either or both were stationary; but both are constantly changing, the one by diffusion and currents, the other by circulation; hence equilibrium is never established, and the respiratory gas-interchange between the blood and the air in the lungs is continuous throughout the whole of life.

INTERNAL OR TISSUE RESPIRATION.—The question still remains to be answered: "What is the ultimate destiny of the oxygen removed from the air, and what is the source of the carbon dioxide added to it?" After it was conclusively shown that the formation of carbon dioxide did not take place in the lungs, it was supposed that its formation took place in the blood in all parts of the body, the oxygen taken up in the lungs serving to oxidize the waste matter poured into the blood. This view was found to be untenable, for very easily oxidizable substances, like pyrogallic acid, do not become oxidized when placed in the blood of a living animal;[12] and if the arterial blood is followed in its course throughout the body, it is found that while the blood in the arteries is of nearly uniform character, as soon as it comes into intimate contact with the tissues in the capillaries the oxygen markedly diminishes, and the carbon dioxide greatly increases, in amount. That the oxygen diminishes in amount during its passage through the tissues may be demonstrated on a living animal by examining the light which traverses some thin membrane like a frog's web, or the wing of a bat, through a spectroscope. The light will show the two bands characteristic of oxyhæmoglobin (see articles Blood and Blood-Stains, vol. i.). If the leg of the frog, or the wing of the bat, is compressed sufficiently to stop the circulation, the single band characteristic of reduced hæmoglobin will soon appear, showing that the oxygen has been given up by the oxyhæmoglobin. According to Vierordt[10] the same may be observed in man by examining through a spectroscope the light which traverses the crack between two fingers. The two bands of oxyhæmoglobin will appear as long as the blood circulates freely; but if a string be wound tightly around the fingers, thus stopping the circulation, the single band of reduced hæmoglobin will soon appear. These demonstrations do not show, however, that the waste material was not first poured into the blood of the capillaries and oxidized there. That it is the tissues that take up the oxygen and give out the carbon dioxide, and that the carbon dioxide is not produced in the blood, is definitely proven by the following: If a living tissue, muscle for example, is removed from an animal and deprived of blood, and placed in a vacuum, or an atmosphere of pure nitrogen or hydrogen, the muscle will continue to produce carbon dioxide, and if irritated will contract, showing that it is alive. If it

* *Partial Pressure, Tension.*—Although these subjects belong to physics, a brief consideration of them may not be out of place, since the terms are so often used in discussing the interchange of gases in respiration. So far as a mixture of gases, unconnected with liquids, is concerned, these two expressions are used interchangeably. The meaning is, that as gases in a mixture exert no pressure upon each other, each exerts such a pressure or has such an expansive force as though it existed alone. This expansive force or pressure is expressed in millimetres of mercury, measured at the standard temperature and pressure (temp., 0° C.; bar., 760 mm. hg.); hence, the partial pressure or tension of a gas in a mixture is obtained by multiplying the atmospheric pressure by the percentage volume of the given gas. Thus, the oxygen of the air forms 20.81 per cent. by volume of the atmosphere; hence its partial pressure or tension is 760 × 20.81 per cent. = 158.156 mm. hg. Knowing the partial pressure in millimetres of mercury, the corresponding percentage by volume is readily obtained by reversing the above process; thus, 158.156 ÷ 760 = 20.81, the per cent. by volume desired.

When a gas is dissolved in a liquid, the term tension alone is applied to it. This means the force by which the gas tends to escape from the liquid. The tension in this case is also expressed in millimetres of mercury or in percentages by volume of the gas. When either of these is known, the other is obtained, as described above for the partial pressure of a gas in a mixture. The tension in millimetres of mercury and the corresponding percentage by volume indicate the amount of the given gas which should be present in an atmosphere overlying the liquid, in order that none of the gas shall escape from the liquid and that no more shall be absorbed. It has no reference to the absolute amount of gas absorbed by a liquid. That varies with each liquid and each gas.

In general, in two gases, a gas and a liquid separated or not by a membrane, or in two liquids separated by a membrane, if there is a difference in the tension or partial pressure of the same gas in the two situations, or a difference in the tension of the given gas in the liquids, or in the liquid and the overlying air, there will be a diffusion of gas from the situation in which the given gas is at the higher, to that in which it is at the lower, tension, and this will continue until equilibrium is established. On the other hand, if the tension is already the same in the two situations, no diffusion of the gas will occur.

is placed in an atmosphere of oxygen or in the air, oxygen will be taken up directly, and carbon dioxide be given off directly, as described in the direct respiration of the amœba, etc. If muscle or other living tissue is placed in arterial blood, some of the oxygen will disappear, and carbon dioxide will appear in its place. Finally, Oertmann and Pflüger have shown that in frogs in which the blood had been entirely replaced by normal salt solution, the respiratory changes take place in a normal manner for a considerable time, and are nearly as great as when the blood was present.

From the facts just stated, and many others, physiologists feel warranted in asserting that the tissues take up the oxygen and give off the carbon dioxide—that is, the true respiratory process occurs in them, and not in the lungs or in the blood. If the first knowledge concerning respiration had been obtained from animals in which

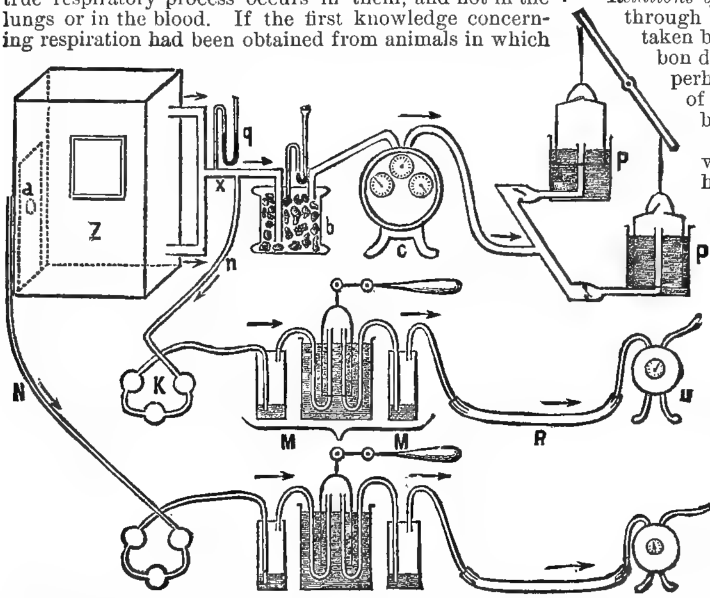

FIG. 3318.—Pettenkofer's Respiration Apparatus. (Landois.) a, opening in the respiration chamber for the entrance of air; b, vessel containing pumice-stone saturated with sulphuric acid, for drying the expired air; C, gas-meter for measuring the air from the respiratory chamber after it is dried; K, bulb containing sulphuric acid to dry the expired air that is to be analyzed; M, M, suction apparatus constructed on the principle of Müller's mercurial valve, and driven by a steam-engine; n, small tube conducting part of the air from the respiratory chamber to the analyzing apparatus, where its composition is determined; N, apparatus for analyzing the air before it enters the respiratory chamber; P, P, double suction-pump, driven by a steam-engine, for drawing the air through the respiratory chamber; q, manometer; R, tube filled with a standard baryta solution, for determining the carbon dioxide; u, small gas-meter to measure the analyzed air, less the carbon dioxide and the watery vapor; x, exit-tube from the respiratory chamber. The air from both the top and the bottom of the respiratory chamber is drawn into this tube, so that it shall be of an average quality; Z, respiratory chamber in which the person or animal remains during the experiment.

the respiration is direct (see above), no respiratory blood or elaborate apparatus being present, it would have been seen from the beginning that respiration is solely for the tissues, no matter how elaborate the appliances for supplying the oxygen and removing the carbon dioxide.[1,6,8,9,12]

The laws governing the gas interchange between the blood in the capillaries and the tissues are supposed to be the same as those obtaining in the lungs, viz., the oxygen-tension in the tissues and the lymph bathing them is far lower than in the blood-plasma, hence diffusion toward the tissues occurs. This goes on until the oxygen-tension in the plasma is so low that the dissociation of some of the oxyhæmoglobin follows, raising once more the tension in the plasma above the dissociating point; but as the tissues are continually taking the oxygen and combining it, the oxygen-tension of the plasma soon falls again below the dissociating point, and more oxygen is given off to it by the oxyhæmoglobin. This process is continuous, for as fast as the oxygen comes into combining distance in the tissues, it is united in a compound more stable than oxyhæmoglobin; consequently, no matter how low the oxygen-tension may fall in the lymph surrounding the tissues, the oxygen compounds formed by them are not dissociated, and the oxygen-tension in the tissues outside the blood-vessels is always lower than in the blood; consequently the diffusion of the oxygen is always away from the blood toward the tissues.

The carbon dioxide in the tissues and lymph surrounding them is at a considerable, and always increasing, tension, while in the blood it has practically no tension, as it is all in combination, and there is a continuous diffusion of the carbon dioxide from the position of higher tension in the tissues to that of a lower tension in the blood.

The blood itself is a tissue, and all the respiratory processes go on in it as in any other tissue.

Relations of the Oxygen in the Tissues.—The changes through which the free oxygen passes after it is taken by the tissues, before reappearing in the carbon dioxide or other excretory product, belongs, perhaps, more properly to the general subject of nutrition, yet a brief discussion may not be out of place here.

The oxygen is probably combined, in some way, with other chemical substances into the highly potential or explosive forms of matter which, in breaking up, give rise to the special form of activity characteristic of the special tissue, and leave less potential compounds, one of which is invariably carbon dioxide. This is shown from the fact that if a muscle, for example, is removed from the body, and freed from blood, it yields no oxygen to the mercurial pump, showing that neither free oxygen nor that loosely combined is present; yet the muscle will contract vigorously when stimulated, and it gives off carbon dioxide continuously—more during the contraction than at rest. As there was no free oxygen present, the carbon dioxide must have been formed by the breaking up of some compound containing oxygen previously stored in the tissue. That this is also true of an entire animal, as well as for the individual tissues, was proved by Spallanzani, Edwards, and Pflüger, who kept frogs, at a low temperature, in an atmosphere of pure nitrogen or hydrogen, for several hours—that is, much longer than the slight amount of oxygen remaining in the air of the lungs or in the blood could have lasted—yet the animals continued to live and produce carbon dioxide. This could not have been the case if oxygen had not been stored in the tissues previous to the experiment.

From what was said under the head of *External Respiration* it is evident that the free oxygen disappearing from the air in the lungs is not immediately returned to the same air, combined with carbon, in the form of carbon dioxide, for it has been shown that this combination does not take place in the lungs; so, likewise, the carbon dioxide returned to the blood of the capillaries does not contain the same oxygen that had been just taken up from the blood by the tissues; but it may have been stored in them, forming part of their living substance for a considerable time. The time intervening between the absorption of the oxygen and its reappearance in the carbon dioxide depends, no doubt, somewhat on the bodily activity of the animal. It is certain that man and the other warm-blooded animals, in which the processes of life are carried on with great vigor, can endure the deprivation of oxygen as well as of other food for a shorter time than the cold-blooded animals.

The Respiratory Income and Outgo, and the Circumstances Affecting Them.—As the oxygen disappearing and the carbon dioxide appearing in respiration have been traced to the tissues, the respiratory activity of

the tissues can be ascertained by determining the amount of oxygen supplied to them and the carbon dioxide excreted. A determination of the total gas-interchange in the lungs will not, however, give the total amount of oxygen absorbed, and of carbon dioxide excreted, as there is a considerable gas-interchange taking place through the skin and through mucous surfaces other than the lungs. The respiratory interchange through the skin, in man and the other animals with a thick and comparatively dry epidermis, is a very small fraction (about $\frac{1}{200}$) of that taking place in the lungs. According to the determinations of Aubert and Lange, the average amount of carbon dioxide excreted by the skin in twenty-four hours is about four grams, or 2,000 c.c. This amount is increased by an elevation of temperature in the surrounding air. Part of this carbon dioxide is not due to respiration, but to decomposition going on at the surface of the skin (Hoppe-Seyler [13]). The amount of oxygen absorbed by the skin is less than the carbon dioxide excreted in the proportion of 100 c.c. of oxygen to 128 to 610 c.c. of carbon dioxide.[6,8]

It is comparatively easy to determine the amount of respiratory gas-interchange going on in the lungs and through the skin; but it is difficult or impossible to determine directly the change through the mucosa of the nose and that of the alimentary canal from swallowed air; consequently, in determining the total respiratory changes going on in an animal, such a method as that of Pettenkofer's, in which the entire income and outgo of the animal is ascertained, must be used (Fig. 3318). It is desirable, however, to estimate the part taken in the total gas-exchange by the different organs involved, so that the part played by each may be known.

In the method of Pettenkofer the amount of carbon dioxide excreted is determined directly, but the amount of oxygen absorbed is determined indirectly, as follows: To the weight of the person or animal at the beginning of an experiment is added the weight of solid and liquid nourishment taken during the experiment; this sum is then subtracted from the weight of the body at the end of the experiment, plus the solid, liquid, and gaseous excreta. The difference represents the oxygen used by the animal during the experiment.

From data furnished in the table in the next column, and by other investigators, the total amount of oxygen taken up by an adult man in 24 hours averages about 750 grams (523,088 c.c.), and the carbon dioxide excreted in the same time averages about 900 grams (456,514 c.c.). The oxygen reappearing in the carbon dioxide is considerably less than that absorbed during the same time. This may be readily seen by comparing the volume of the two gases, as one volume of oxygen when united with carbon forms but one volume of carbon dioxide gas. The diminished amount of the oxygen appearing in the carbon dioxide is explained from the fact that part of the absorbed oxygen is used in forming compounds other than carbon dioxide.

TABLE FROM PETTENKOFER AND VOIT, SHOWING THE TOTAL GAS-EXCHANGE, THE RESPIRATORY QUOTIENT, AND THE AMOUNT OF WATER EXCRETED IN TWENTY-FOUR HOURS BY A MAN UNDER VARIOUS CONDITIONS OF FOOD AND ACTIVITY: [13]

Diet, etc.	Carbon dioxide excreted.		Oxygen absorbed.		Respiratory quotient.		Water excreted.

Following Pflüger, most physiologists designate the relation or ratio between the volume of carbon dioxide excreted and the volume of oxygen absorbed in a given time as the respiratory quotient $\left(\frac{CO_2}{O}\right)$. This ratio varies considerably with different conditions of the body, as will be seen below and by consulting the table above.

The respiratory activity of man is greater than that of animals larger than himself, but less than that of many at least of the warm-blooded animals smaller than himself, as will be seen from the following table. In this table the amounts given represent what each animal, retaining its normal respiratory activity, would show if it weighed one kilogram and the experiment continued one hour: [8]

Name of animal and total weight in kilograms.	Oxygen absorbed per hour and kilogram.		Carbon dioxide excreted per hour and kilogram.		Respiratory Quotient, $\frac{CO_2}{O}$	Authority.
	Grams.	Cubic centimetres.	Grams.	Cubic centimetres.		
Man, 60	0.518	361	0.619	314	0.869	Speck.
Ox, 650	...	...	0.437	217	...	Pettenkofer and Voit.
Bull-calf, 115	0.481	336	0.571	290	0.862	Reiset.
Sheep, 66	0.490	343	0.671	341	0.994	"
Dog, 6.393	1.164	814	1.188	604	0.742	Regnault and Reiset.

Cockchafers	1.076	752	1.1699	594 8	0.791	" "

Conditions Affecting the Respiratory Gas-interchange.—Bodily activity of any form exerts two influences: the absolute amount of oxygen absorbed and of carbon dioxide excreted are both greatly increased. The relative amount of the two gases is more nearly equal during action than at rest. In some cases of activity and apparent rest this quotient may approach or even exceed unity, showing that oxygen stored at some previous time is being drawn upon (see table from Pettenkofer and Voit).

Sleep and *hibernation* being conditions of profound repose, the respiratory activity is greatly lessened. The relative amount of oxygen absorbed increases in most cases, showing that oxygen is being stored for future use. The respiratory quotient consequently falls considerably below unity. In hibernating animals this quotient may fall below one-half (0.399 to 0.588, Regnault and Reiset).

During digestion the respiratory activity is increased, the amount of carbon dioxide approximating more closely to the amount of oxygen absorbed than when fasting. This is especially true if a vegetable diet is taken in which there is considerable starch. In fully-fed animals there appears to be also a slight excretion of nitrogen

through the lungs. In fasting animals nitrogen appears to be absorbed in small quantities in the lungs.

The respiratory activity is greater in children than in adults, in boys than in girls, in men than in women. The absolute amount increases with age and body weight in both sexes until puberty. In women it then remains nearly stationary (except during gestation, when it is greatly increased) until the cessation of the menses, when it increases for a few years. In men there is a gradual increase until the thirtieth or thirty-fifth year, then nearly a standstill until about the fiftieth year. Beyond fifty there is in both sexes a gradual decrease in the respiratory activity, following the decrease in general bodily activity.[6,14]

TABLE FROM SCHARLING [8] SHOWING THE VARIATION IN RESPIRATORY ACTIVITY IN PERSONS OF DIFFERENT AGE AND SEX.

Age and sex; weight in kilograms.	Carbon dioxide excreted in twenty four hours.	Carbon dioxide excreted per hour and kilogram.
	Grams.	Grams.
Man, age, 35 years; weight, 65.5 kilos.......	804.72	0.512
Soldier, age, 28 years; weight, 82 kilos	878 95	0.497
Boy, age, 16 years; weight 57.75 kilos	822.69	0 594
Woman, age, 19 years; weight, 55.75 kilos ..	608.22	0 455
Boy, age, 9¾ years; weight, 22 kilos	488 14	0.925
Girl, age, 10 years; weight, 23 kilos	459.87	0.833

Man and the other air-breathing animals have become so accustomed to the mixture of oxygen and nitrogen found constantly in the air, that this mixture is undoubtedly the best adapted for health and comfort; but owing to the fact that the absorption of oxygen and the excretion of carbon dioxide are regulated by the activity of the tissues, and that they are largely chemical processes, the respiration goes on practically unchanged in widely varying conditions of the atmosphere. In an atmosphere of pure oxygen the respiratory processes go on normally. If the amount of oxygen in the air falls considerably below the amount normally present, there is a feeling of distress, especially upon muscular activity, as the hæmoglobin cannot get the oxygen fast enough, owing to the low oxygen-tension in the air and its consequent slow absorption by the blood-plasma. Thus, in an atmosphere containing less than fourteen per cent. of oxygen dyspnœa occurs upon exertion; if it contains but seven per cent., breathing in repose is difficult; and if it falls to three or four per cent. there is rapid asphyxia, although there is no excess of carbon dioxide. The asphyxia produced by lack of oxygen is accompanied by violent spasms, while that resulting from an excess of carbon dioxide, when plenty of oxygen is present, is not usually accompanied by spasms.[6]

By a greatly diminished atmospheric pressure the respiratory gas-interchange is diminished in rapidity, and by an increased pressure it is increased. If the pressure of the atmosphere falls below two hundred and fifty millimetres of mercury warm-blooded animals soon die, owing in part to the slowness with which the oxygen comes into combining distance with the hæmoglobin, and, according to Hoppe-Seyler, in part to the liberation of bubbles of gas in the blood, and the consequent plugging of the blood-vessels. Under an increased atmospheric pressure the oxygen enters the blood-plasma more rapidly, and hence comes into combining distance with the hæmoglobin in such quantity that it may be fully saturated, and hence ready to supply the tissues more generously than under ordinary circumstances. If the pressure is too great (ordinary air at a pressure of fifteen atmospheres, pure oxygen under a pressure of three atmospheres) the animal dies of asphyxia, as if no oxygen were present. This is comparable with the non-combustibility of phosphorus in pure oxygen, and its ready combustibility when the oxygen is diluted with nitrogen, or if it is diminished in pressure.[6,8]

Variations in temperature have a marked effect in changing the respiratory activity. In cold-blooded animals the respiratory activity is in direct proportion to the rise in temperature up to the maximum not inimical to health. With the warm-blooded animals, in which the body temperature is maintained at a nearly uniform standard, the respiratory activity is lessened with an increase of temperature, and increased with a diminution of temperature.

WATER, ORGANIC MATTER, ETC., EXCRETED BY THE LUNGS.—Strictly considered, the excretion of water and other substances from the lungs may not properly belong to the subject of respiration; it is usually so included, however, as the excretion takes place from organs which are primarily organs of respiration, and it is a constant accompaniment of breathing. Under ordinary circumstances there is given off by the lungs about one litre of water in twenty-four hours. This water is derived from the mucous surface of the lungs and the air-passages. The amount of water required to saturate the breath with moisture depends largely upon the hygrometric conditions of the atmosphere. That is, if the air contains very little moisture a great deal must be added to it in the lungs to bring it to the point of saturation at the temperature of the body. On the other hand, if the air is warm and nearly saturated with aqueous vapor, only a little will be necessary to complete the saturation. If the air is warmer than the body, and saturated with moisture, it will be cooled in the lungs, and water will be deposited until the point of saturation at the lower temperature is reached. That is, the expired air may be cooler, and contain less watery vapor than the inspired air, but this is uncommon. Air containing considerable moisture is more comfortable to breathe than dry air. If it contains too much moisture there is produced a feeling of closeness, and if too little, the evaporation from the air-passages is so rapid that they become parched. For this reason it is more comfortable to sit in an artificially heated room in which watery vapor is constantly mixed with the heated air.

In addition to the watery vapor exhaled, there is constantly a small amount of organic matter given off with the breath. The exact nature and amount of this organic matter have not been determined, owing to the difficulty of so doing. It is this substance which produces the chief deleterious effects in breathing air over and over. The amount of carbon dioxide present in a room containing several individuals is usually not sufficient to produce any serious effects, as is shown by the continuous breathing of air containing a considerable amount of carbon dioxide by men when mining coal. The carbon-dioxide tension in the air of an inhabited room, however, is a good guide as to the wholesomeness of the air, for, if the carbon dioxide was produced in breathing, the air will also be loaded with the more dangerous organic matter, which cannot be so readily estimated. The lungs may also act as excretory organs in eliminating sulphuretted hydrogen and ammonia from the system, and also alcohol and various essential oils, like turpentine and those giving the odor to garlic, etc., which had been previously taken into the stomach.[5]

MECHANICS OF RESPIRATION.—Under this heading are included all the movements necessary for the supply of the respiratory organs with pure air and the removal of that which has become vitiated. For this respiratory ventilation, as it is often called, two very definite acts occur—*inspiration*, or breathing air into the lungs, and *expiration*, or breathing air out of the lungs.

Inspiration.—This is forcing air into the lungs, and is brought about entirely by muscular movement, as follows: The glottis is widely opened, rendering the passage to the lungs free; the diaphragm contracts, thereby flattening its arch and increasing the cavity of the thorax lengthwise (Fig. 3319). At the same time the muscles attached to the curved and sloping ribs contract, rotating and raising the ribs, and thus enlarging the thorax in its two transverse diameters (Fig. 3320). The enlargement of the thoracic cavity lessens the atmospheric pressure within it, and as there is no communication between the thoracic cavity and the air, the air rushes into the elastic lungs through the air-passages; the lungs stretch and completely fill the enlarged cavity in the thorax.

Expiration.—This is forcing the air out of the lungs.

In normal breathing it follows inspiration without a pause, and is brought about, in quiet breathing, by the relaxation of the inspiratory muscles, the weight of the elevated ribs and chest-walls, and the elasticity of the costal cartilages; by the elasticity of the abdominal walls and the abdominal organs; and, finally, by the elasticity of the lungs, which were put on the stretch during inspiration.

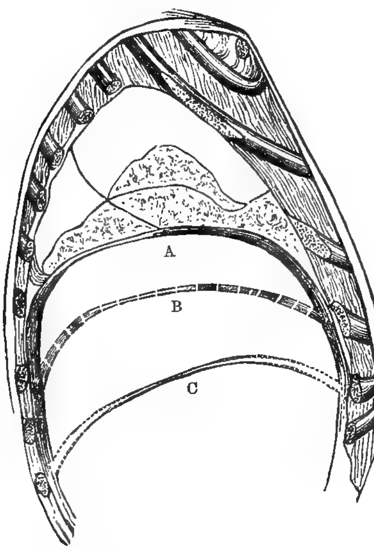

FIG. 3319.—View of the Thorax, with the left side removed to show the position of the diaphragm in various phases of inspiration and expiration. (Rosenthal.) A, position of the diaphragm in strong expiration; B, its position in moderate, and C, in deep inspiration.

Whenever, by any form of bodily activity or any other cause, the lungs cannot be thus sufficiently ventilated, the respiratory movements become more vigorous and the respiration is said to be labored. Whenever this occurs, muscles not employed in quiet inspiration are brought into action, and the expiration is no longer due to gravity and elasticity alone, but is aided by muscular contraction.

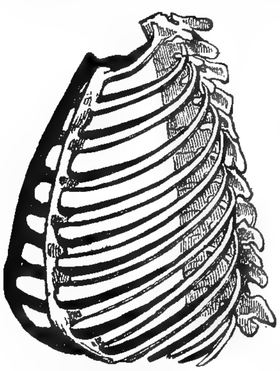

FIG. 3320.—View of the Left Side of the Skeleton of the Thorax, showing the position of the ribs and sternum in expiration (light shading) and in inspiration (dark shading). (Béclard.)

In the following list are given the muscles which aid directly in inspiration by making the thoracic cavity larger, or in expiration by diminishing that cavity; or they may aid indirectly by furnishing fixed supports for other muscles which can act directly on the thorax with more advantage thereby; or they may assist by opening more widely the air-passages. This list, which also gives the nerves supplying the muscles, is copied from Landois.[6]

Ordinary Inspiratory Muscles (the muscles in action during quiet breathing): The diaphragm (*nervus phrenicus*); the Mm. levatores costarum longi et breves (*Rami posteriores, Nn. dorsalium*); the Mm. intercostales externi et intercartilaginei (*Nn. intercostales*).

Auxiliary Inspiratory Muscles (muscles brought into action during labored and forced inspiration).

(A) The ordinary inspiratory muscles named above.

(B) *Muscles of the Trunk:* The three Mm. scaleni (*Rami musculares of the plexus cervicalis et brachialis*); M. sternocleidomastoideus (*Rami externus, N. accessorii*); M. trapezius (*R. externus, N. accessorii et Ram. musculares plexus cervicalis*); M. pectoralis minor (*Nn. thoracici anteriores*); M. serratus posticus superior (*N. dorsalis scapulæ*); Mm. rhomboidei (*N. dorsalis scapulæ*); Mm. extensores columnæ vertebralis (*Ram. posteriores nervorum dorsalium*); Mm. serratus anticus major? (*N. thoracicus longus*).

(C) *Muscles of the Larynx:* M. sternohyoideus (*Ram. descendens hypoglossi*); M. sternothyroideus (*Ram. descendens hypoglossi*); M. crico-arytenoideus posticus (*N. laryngeus inferior vagi*); M. thyreo-arytenoideus (*N. laryngeus inferior vagi*).

(D) *Muscles of the Face:* M. dilator narium anterior et posterior (*N. facialis*); M. levator alæ nasi (*N. facialis*); in gasping for breath the dilators of the mouth and nares.

(E) *Muscles of the Pharynx:* M. levator veli palatini (*N. facialis*); M. azygos uvulæ (*N. facialis*).

Muscles in Action during Labored Expiration: The abdominal muscles, including the obliquus externus and internus, and transversalis abdominis (*Nn. abdominis internis anteriores e nervis intercostalibus*, 8th to 12th); Mm. intercostales interni, so far as they lie between the osseous ribs,* and the infracostales (*Nn. intercostales*); M. triangularis sterni (*Nn. intercostales*); M. serratus posticus inferior (*Ram. externi nerv. dorsalium*); M. quadratus lumborum (*Ram. musculare e plexu lumbali*).

Rate of the Respiratory Movements, Apnœa.—According to the numerous observations of Hutchinson,[16] Sibson, and others, in quiet breathing there occur in the adult from eighteen to twenty inspirations and expirations per minute, or about one breath for every four heart-beats. The number of respirations, that is, the number of inspirations and expirations, is greater in children than in adults, and in those in the prime of life than in old age. In small animals, like the rat, the rate is far greater than in man (100 to 200 per minute), while in some at least of the larger animals it is slower than in man (rhinoceros, 6 per minute).[9]

Any circumstance increasing bodily activity in any form causes an increased rapidity of the respiratory movements to supply the extra oxygen demanded, and to remove the extra carbon dioxide formed. If the number and depth of the respirations are increased voluntarily, the total amount of oxygen absorbed and of carbon dioxide exhaled is not increased beyond what is due to the extra muscular exertion required in so breathing; for the respiratory gas-interchange is controlled entirely by the tissues, not by the respiratory movements. The expired air will, however, contain less carbon dioxide and more oxygen than usual, as the carbon dioxide excreted is more largely diluted by the extra amount of air, and the larger amount of air supplying a definite amount of oxygen is less impoverished than a smaller amount would be. If one breathes deeply and rapidly for a short time, it is easier to hold the breath for a considerable time afterward than when breathing ordinarily. Somewhat similarly, if artificial respiration be performed on an animal—a rabbit, for example—that has been in nowise injured, the animal will remain, for a considerable time after the artificial respiration has ceased, without breathing; the respiratory movements will then commence, and gradually increase in vigor until the animal breathes in a normal way as before the artificial respiration. It has been demonstrated, in one case at least, that a human being will show the same phenomena under the influence of artificial respiration after tracheotomy.[21] This cessation of breathing has been designated *apnœa* by Rosenthal.[18] It has received three explanations: (1) That of Rosenthal, who supposes that on account of the purity of the air in the lungs produced by the extra ventilation, the hæmoglobin of the blood becomes entirely saturated with oxygen, and this supply lasts for a considerable time before more is needed to keep the blood up to the ordinary standard of purity. (2) That of Gad,[6] who

* The controversy begun by Haller and Hamburger concerning the action of the internal intercostal muscles is still continued. At present, however, the majority of physiologists agree with Hamburger that the internal intercostal muscles between the bony part of the ribs act as expiratory muscles, while those between the costal cartilages act as inspiratory muscles.

supposes that on account of the purity of the air in the lungs the blood can get all the oxygen needed, and get rid of its carbon dioxide for a considerable time without further ventilation of the lungs. (3) That of Hoppe-Seyler,[13] who thinks the cessation of breathing is due to the exhaustion of the respiratory muscles. This view seems less satisfactory than either of the others, for in the case of the rabbits no muscular exertion was required on their part to exhaust their respiratory muscles, and furthermore, muscular activity tends to increase, not diminish, the rapidity of the respiratory movements.

Rhythm and Type of the Respiratory Movements.—In normal quiet breathing, beginning with inspiration, inspiratory movements are rapid and continuous, then expiration follows without a pause, but proceeds more slowly than inspiration, the ratio being, inspiration six, expiration seven, for adult men. In women, children, and the aged the ratio is, inspiration six, expiration eight or nine (Sibson). After expiration there is in many

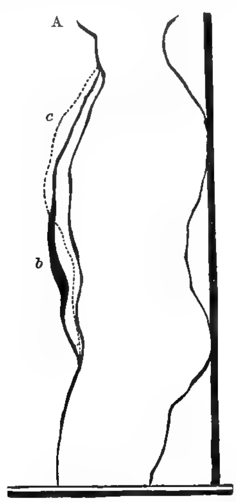

FIG. 3321.—Diagrams Showing the Change in Form of the Thorax and Abdomen during Respiration in the Male and the Female. (Hutchinson.) A, outlines of the male, and B, outlines of the female figure, indicating the different phases of the respiratory movements; *a*, *a*, outline of the body in full expiration; in this condition the lungs contain only the residual air. *b*, *b*, heavy continuous line; the outer margin indicates the contour of the body in ordinary inspiration, and the inner margin in ordinary expiration; the thickening of the line over the abdomen in the male, and over the thorax in the female, indicates that the greater movement occurs in the abdomen of the male (abdominal type of respiration), and in the thorax of the female (costal type of respiration); the entire thickness of the line represents the amount of tidal air; in ordinary inspiration the lungs contain the residual, the reserve, and the tidal air. *c*, *c*, dotted line giving the contour in the deepest inspiration; the thorax is greatly expanded, but the abdomen is less so than in ordinary expiration; in the deepest inspiration the lungs contain the residual, the reserve, the tidal, and the complemental air (see below).

cases a slight pause (expiration-pause) before the beginning of the following inspiration. This pause is not always present, and is always absent except in quiet breathing. The movements of a complete respiration are then, (1) a rapid continuous inspiration, (2) a somewhat slower expiration immediately following the inspiration, (3) in many cases a slight pause before the following inspiration.

The respiratory movements in some individuals are more especially due to the elevation of the ribs, and in others to the contraction of the diaphragm; consequently these movements have been divided into two corresponding types by Hutchinson,[16] viz., *costal respiration*, in which the enlargement of the chest is due largely to the elevation of the ribs, and *abdominal respiration*, in which the chest-cavity is enlarged most by the contraction of the diaphragm, with the consequent movements of the abdominal walls. The costal type is most common in women, the abdominal type in men. In children of both sexes there is no marked difference in type, and in the adult the differences are only noticeable in quiet breathing. In labored breathing the movements of the chest are most noticeable in both sexes (Fig. 3321).

Two explanations have been offered for the great prevalence of the costal type in the female: (1) That it is due to the habitual use of tight clothing around the waist; and (2) that it is a kind of reservation against the period of gestation. Hutchinson found the costal type marked in twenty-four girls, varying from eleven to fourteen years, who had never worn tight clothing around the waist.[16] On the other hand, Mays[22] found by careful experiments, made according to the graphic method, that in eighty-two North American Indian girls, varying from ten to twenty-two years, the abdominal type of breathing was marked in nearly every case. The experiments of Mays would indicate that the primitive and natural type of respiration in the female, as well as in the male, is the abdominal; but in comparing the observations of Mays and Hutchinson on subjects which had

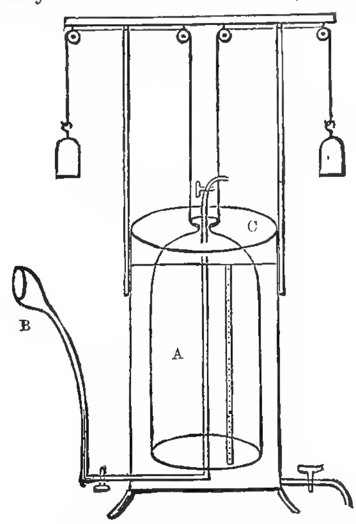

FIG. 3322.—Diagram of Hutchinson's Spirometer. (Landois.) A, graduated cylinder serving as a receiver for the breath; it is supplied with a stop-cock at the top for the ready expulsion of air, and is balanced by weights passing over pulleys. B, mouth-piece with tube reaching nearly to the top of the graduated receiver (A), when the latter is sunk in the reservoir ready for an experiment; there is a stop-cock in this tube near the first angle to prevent regurgitation of air. C, reservoir for the graduated receiver. In using the spirometer the reservoir and graduated receiver are filled with water, or, to prevent the absorption of carbon dioxide, with a saturated aqueous solution of common salt (NaCl.). When ready for an experiment, the stop-cock at the top of the receiver is closed and that in the tube of the mouth-piece opened, and the breath forced into the receiver. The receiver rises as fast as the breath displaces the water. After the breath is forced into the receiver the stop-cock in the tube of the mouth-piece is closed, and the water outside and inside the receiver brought to the same level, so that the air within the receiver shall be at the atmospheric pressure The amount of breath within the receiver is then read directly from the scale attached to the receiver. For accurate measurement the breath should stand a few minutes to acquire the temperature of the liquid over which it is collected, then the various corrections for aqueous vapor tension, and the variations from the standard temperature and pressure, should be made.

been equally free from the effects of tight clothing, it would appear that the type of respiration may differ in the females of different races.

Respiratory Ventilation.—In very young children the lungs are nearly emptied at each expiration, so that the ventilation is nearly complete; but after the first period of infancy a large amount of air remains constantly in the lungs, and only a limited amount of this is changed at each breath. Hutchinson and others have investigated with great assiduity the question as to the total capacity of the lungs, the amount of air in them under various conditions, the amount of air inspired and expired at each breath, etc. When the subject was first studied there were great hopes that it would give valuable aid in discovering and treating disease, but these anticipations were not realized. Its chief value is in hygiene; for, by

showing how much air is breathed by an individual in an hour, and knowing by analysis the contamination of the air due to being breathed once, data are furnished for the ventilation of rooms and buildings. For determining the various amounts of air expired under various conditions, Hutchinson [16] invented a kind of gasometer, called by him a *Spirometer* (Fig. 3322). In the following table is shown diagrammatically the relative position and amount of the different volumes of air that may be in the lungs at the same time.

Total capacity of the lungs, 5,300 c.c.	Breathing or vital capacity, 3,700 c.c.	Complemental air, 1,600 c.c.	
		Breathing or tidal air, 500 c.c.	
		Reserve air, 1,600 c.c.	Stationary air, 3,200 c.c.
	Residual air, 1,600 c.c.	"Collapse" air, 800 c.c.	
		"Minimal" air, 800 c.c.	

Complemental air is the amount of air that may be inspired after an ordinary inspiration.

Breathing or tidal air is the air inspired and expired at an ordinary breath.

Reserve air is that which may be expired after an ordinary expiration.

Residual air is that which cannot be expelled from the lungs by the most forcible expiration. It is composed of two nearly equal portions, the "*Collapse*" *air*, which escapes from the lungs when the chest is freely opened, and "*Minimal*" *air*, that which remains in the lungs after the thorax is opened.

Breathing or vital capacity. This is the amount of air which may be forced from the lungs after the deepest possible inspiration. It is the sum of the reserve, the tidal, and the complemental air.

Stationary air. This is the sum of the reserve and the residual air, and is so named as, under ordinary circumstances, these two volumes of air remain constantly in the lungs.

Many experiments have been tried to determine the amount of change of the air in the lungs by a single breath. From the nature of the problem no method is wholly satisfactory. The one originally proposed by Davy is most used. It consists of inhaling a known volume of pure hydrogen, and then analyzing the expired air. If no mixing of the hydrogen with the air already in the lungs takes place, then the expired gas, like the inspired, would be pure hydrogen. By actual experiment it is found that, supposing 500 c.c. of pure hydrogen are inhaled, only 170 c.c. of hydrogen are exhaled, the remaining 330 c.c. being air. That is, 330 c.c. of the inhaled hydrogen displace the same amount of air. If, now, it is assumed that in ordinary breathing 500 c.c. of air are inhaled, and the 330 c.c. of this remain as with the hydrogen, and displace a similar amount of vitiated air, then the amount of renewal must be the ratio between the air in the lungs before the inspiration—that is, the reserve and the residual air (3,200 c.c.), and the fresh air (330 c.c.) remaining in the lungs after each expiration—$\frac{330}{3200} = 0.103$. This has been termed the coefficient of ventilation,[8] and in the case given shows that only about one-tenth of the air in the lungs is changed at each breath. The intermixture of this fresh tidal air with the reserve air in the air-passages is due largely to the currents produced by inspiration, but the residual air in the alveoli and smallest air-passages must depend mostly on diffusion for its purification. This diffusion is no doubt greatly facilitated by the swaying to and fro of the air as the chest alternately expands and contracts, to the jars produced by the heart-beats and the pulsation of the pulmonary arterioles, and also to the ciliary currents in the bronchi. It would seem reasonable to suppose, therefore, that the air in the alveoli remains of a nearly uniform quality, and that it contains a greater percentage of carbon dioxide, and a less percentage of oxygen than the expired air. The direct experiments of Wolfberg and others, however, show that there is but little difference in the composition of the alveolar air and that which may be expired by a full expiration. This seems to show that the diffusion in the lungs is very rapid.[8]

Pressure in the Air-passages.—This varies in inspiration and expiration. It is measured by connecting a manometer with the nose or mouth, or, in an animal, with the trachea, and noting the variations in the columns of mercury during inspiration and expiration. In man, when there is a perfectly free entrance for the air to the lungs, the aspiration, suction, or negative pressure during quiet inspiration is about 3 mm. of mercury, and during expiration the positive pressure is from 2 to 3 mm. In forced inspiration the aspiration may reach 57 mm. hg., and in forced expiration the pressure may rise to 87 mm. hg. If the air-passages are closed, so that no air can enter or leave the lungs, then the aspiration or negative pressure is from 30 to 74 mm. hg., when inspiratory efforts are made; and when expiratory efforts are made the pressure is 62 to 100 mm. hg.

The elastic lungs are during life and the complete integrity of the thorax somewhat stretched. If the trachea of a dead person is connected with a manometer and then the thorax freely opened, the elasticity of the lungs will show a pressure of 6 mm. hg. If the lungs are fully inflated, then the pressure due to their elasticity will be measured by about 30 mm. hg. This shows very graphically the part played by the elasticity of the lungs in expiration.[6,12]

The respiratory sounds and the interaction of the circulatory and respiratory movements have already been treated in this HANDBOOK, the first under Chest, vol. ii., p. 82; the second under Blood-circulation,[17] vol. i., pp. 563, 566.

The Respiratory Centre and the Nerves of the Respiratory Apparatus.—As with all the other muscles and organs of the body those belonging to the respiratory apparatus are well supplied with nerves. The names of the nerves supplying the respiratory muscles are given above in the list of the muscles. It has further been found that the whole complex mechanism of respiration is under the control of a nerve-centre, termed from its office *the respiratory centre;* and from the fact that an animal invariably dies after its destruction, it is called the vital point (*nœud vital*). This centre is situated in the medulla, near the origin of the vagus nerve. While it has been known from the time of Le Gallois [18] that this centre exists in the medulla, the question whether it is a reflex centre, acting only in accordance with afferent impulses from without, either through special nerves like the vagus, or through those from the entire system, or whether it is an automatic centre acting in accordance with changes going on within itself, was for a long time unknown. It is now quite well established that the centre is automatic, although its action may be greatly modified by afferent impulses. It is a matter of common experience that one can cease breathing for a limited time, or can greatly increase the number and depth of the respirations, at will; also that a dash of cold water causes most persons to take a deep breath, and by the application of snuff or dust to the nose a sneeze is produced. So coughing, which is likewise only a modified respiratory act, is induced by an irritation of the glottis, etc. While, therefore, the centre is constantly being influenced from without, the final proof of its automatic action is given by the following experiments:

In 1879 Flint[5] showed that if the thorax of an animal is opened and artificial respiration kept up sufficiently to aerate the blood well, no respiratory efforts are made by the animal; but if the vessels going to the medulla are clamped, cutting off the supply of arterial blood to the respiratory centre, violent respiratory movements are made, although all the rest of the body is well supplied with arterial blood. On the other hand, if clamps are put on the vessels so that oxygenated blood can go only to the respiratory centre, no respiratory movements will be made, although all the rest of the body is suffocating.

Anatomically and physiologically, the respiratory cen-

tr[illegible] is symmetrical, there being one on each side, as is shown by the continuance of the respiratory movements after cutting the medulla longitudinally. If one side of the centre is then destroyed the respiratory movements cease on that side, but continue on the other. There are also many reasons for supposing that the respiratory centre is composed of an inspiratory and an expiratory part, the expiratory part being cephalad, or in front of the inspiratory part.[6, 18]

The stimulus acting on the respiratory centre to arouse its activity seems to be the blood which circulates in it. If this blood contains too small an amount of oxygen the centre sends out stimuli to the inspiratory muscles, and then, slightly later, to the expiratory muscles. An excess of carbon dioxide seems also to have a stimulating effect on the respiratory centre, chiefly the expiratory part (Bernstein).[10] The lack of oxygen is the more potent factor in arousing the respiratory centre, however, as is shown by the fact that the most violent respiratory efforts are made when a deficient supply of oxygen is present in the air supplied to the lungs, although there may be no excess of carbon dioxide. If there is plenty of oxygen in the air, and an excess of carbon dioxide, the animal often dies from carbon-dioxide poisoning, without spasms.

Besides the main respiratory centre in the medulla, other centres, called accessary respiratory centres, have been described as present in the myel or spinal cord, and also in the brain; but at present exact information concerning these centres, if they exist, is very meagre.[6]

REFERENCES.

In preparing this article, constant reference has been made to the English, French, and German journals of physiology, and to the text-books and larger works on physiology and physiological chemistry. The bibliography is especially full in Bert, 9; Gamgee, 20; Milne-Edwards, 19; Reid, 15; Rosenthal, 18; and Zuntz, 8. As some of the authors are referred to several times, the pages are given in the order of the references.

RHATANY (*Krameria*, U. S. Ph.; *Krameriæ Radix*, Br. Ph.; *Radix Rhataniæ*, Ph. G.; *Ratanhia*, Codex Med.). The roots of some species of *Krameria*, especially *K. triandra* Ruiz and Pavon, and *K. Ixina* Linn. (*K. tomentosa* St. Hilaire), order *Polygalaceæ* (*Leguminosæ*, *Krameriæ*, Luerssen).

FIG. 3323.—Krameria Triandra; flowering branch. (Baillon.)

Krameria triandra is a low shrub with a thick, dark-colored, woody, branching root, and straggling, slender, branching stems. These latter are from one-third to one metre in length, the longer reclining or horizontal, the shorter erect; bark grayish-brown, twigs greenish-gray, silky. Leaves alternate, sessile, obovate, lanceolate, spiculate, silky-hairy. Flowers solitary, axillary near the ends of the branches, calyx of four scarlet sepals, cruciform, the lateral sepals shorter than the others. Petals four, also scarlet, the two upper erect, spatulate, the two lower short, broad, and glandular. Stamens three, short and thick. Pistil simple; ovules two. Fruit spherical, silky, and spiny. This species is indigenous to high, sandy slopes in Peru and Bolivia, and is the source of the Red Peruvian Rhatany.

K. Ixina has a larger, smoother, more brown or purplish root, longer leaves, smaller and duller-colored flowers, and five sepals. It grows in the West Indies, and in Central and South America. Its root, which is fully as good as the other, is known as Savanilla, New Granada, or Violet Rhatany. There is very good reason for placing this anomalous genus near the sub-order *Cæsalpinæ* in Leguminosæ.

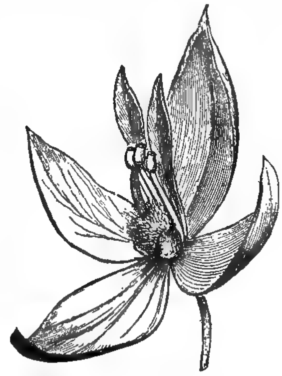

FIG. 3324.—Krameria Triandra; flower. (Baillon.)

Rhatany root was noticed by Ruiz in 1784, as used by the women of Huanaco and Lima for the preservation of their teeth, and by him was introduced into Spain a year or two after (Flückiger), whence it soon became known.

Peruvian Rhatany (root) "is about one inch thick, knotty and several-headed above, branched below, the branches long, bark smooth or scaly, deep rust-brown, about one-twelfth of an inch (2 millimetres) thick, very astringent, inodorous; wood pale-brownish, tough, with fine medullary rays, nearly tasteless. The root of *Krameria tomentosa* (Savanilla Rhatany) is less knotty and more slender, and has a dark purplish-brown bark about one-eighth of an inch (3 millimetres) thick.

Both varieties have essentially the same medicinal

properties and composition. The most important constituent (of the bark—the wood is nearly inert) is *Rhatania-tannic acid*, existing to the extent of about twenty per cent.; a brilliant, deep-red, amorphous mass, soluble in alcohol, incompletely so in water; with perchloride

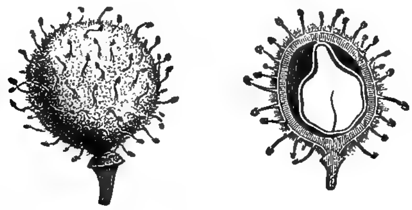

FIG. 3325.—Krameria Triandra; fruit, entire and in section. (Baillon.)

of iron it gives a dull-green color. When exposed to the action of diluted acids, and under other circumstances, this tannin is decomposed into sugar and *Rhatania red.* This substance is much less soluble in water than the tannin, and is also but little soluble in alcohol and ether.

ACTION AND USE.—Rhatany is a reliable and useful astringent, owing to its large per cent. of tannin, and is

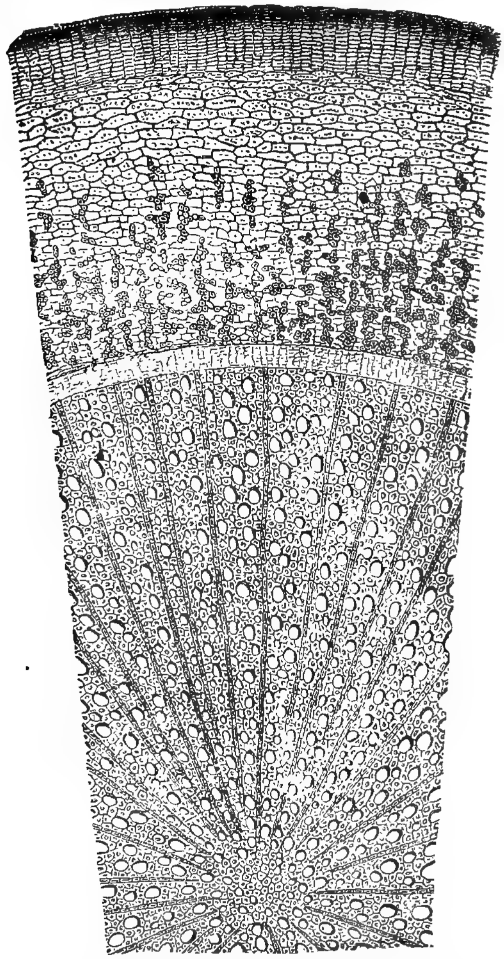

FIG. 3326.—Krameria Triandra; transverse section of root. (Baillon.)

applicable to all the conditions where gallic or tannic acid is useful. The crude drug may be given in powder, but seldom is, as the large amount of woody tissue is a disadvantage. Dose, one or two grams (gr. xv. ad xxx.). The following officinal preparations are all good: Extract (*Extractum Krameriæ*) for pills, strength about $\frac{4}{1}$; Fluid Extract (*Extractum Krameriæ fluidum*), strength $\frac{1}{1}$; and Tincture (*Tinctura Krameriæ*), strength $\frac{1}{5}$.

ALLIED PLANTS.—There are a dozen or more South American species of Krameria, all astringent, and several are in use in the countries where they grow.

ALLIED DRUGS.—See NUTGALLS, CATECHU, etc.

W. P. Bolles.

RHEUMATISM, ACUTE ARTICULAR. *Synonyms:* Rheumatic Fever, Acute Rheumatism, Acute Rheumatic Polyarthritis.

Definition.—Acute articular rheumatism is a specific inflammation which attacks the structures in and around the large joints. As a rule, two or more articulations are affected, and the inflammation moves from one to another. It is scarcely ever followed by suppuration. It is accompanied by severe febrile disturbance. In a large proportion of cases the fibro-serous structures of and about the heart are also affected by the inflammatory process.

History.—This disease has doubtless existed from the earliest ages, but the term rheumatism was first applied to it by M. Baillon, who published a treatise on the subject in 1642. The term was afterward applied by many authors to inflammation of the joints generally. We now distinguish under several heads diseases which formerly, by some, were called rheumatic, viz.: 1, Articular rheumatism; 2, gout; 3, rheumatoid arthritis; 4, muscular, and 5, gonorrhœal, rheumatism.

Articular rheumatism may conveniently be divided into (*a*) acute, (*b*) subacute, and (*c*) chronic forms.

Morbid Anatomy.—Opportunities for making post-mortem examinations in cases of acute rheumatism are rare. The synovial membrane is found congested, the inner surface being rather dull in appearance, with a serous fluid filling the cavity of the joint. This fluid contains masses of epithelium. Occasionally pus is found in the exudation. The structures around the joint are also inflamed. Sometimes the tendinous structures are filled with a yellowish serum. The cartilage often shows signs of inflammation.

Symptoms.—The onset of the disease is marked by different features in different cases. The attack is sometimes preceded by a slight chill followed by fever. In many cases there is a premonitory stage, during which wandering pains occur in the joints, and there is observed a peculiar puffy condition about the ankles. In a few instances the pericardium or endocardium is first attacked. In such cases the patient first notices a sense of oppression, with dull pain, in the chest. When the disease has become established the most prominent symptoms are as follows: Pain and swelling of the larger joints of the body; elevation of temperature with general febrile disturbance; the occurrence of excessive perspiration. The joints most often affected are the knee, elbow, wrist, and the smaller joints of the hands and feet. The hip and shoulder may also be attacked, but the swelling is less apparent in these, owing to their being covered by large muscles. The swelling is often accompanied by some redness and tension. Neither of these latter symptoms is as prominent as in gout. The pain is more or less acute; it is sometimes dull and aching, but more frequently it is severe and excruciating. It is increased by the slightest movement; even the shaking of the bed will make it more intense. The patient is thus rendered quite helpless, and speaks of having lost the use of his limbs. The pain is more severe at night than during the day. The swelling of the joints varies very much in different cases. In some it is but slightly marked, and is not accompanied by much redness, or tenderness on pressure. In others, again, the swelling is excessive, so that the articulation presents a red, shining, tense appearance, very much resembling gout except that the surrounding veins are not enlarged. It is remarkable how quickly the swelling may subside. A joint may present the most severe symptoms on one day, and the next it may have almost resumed its normal condition. The intense inflammation usually lasts four or five days, and on its disappearance other articulations may become affected.

The same joint may be attacked two or three times during the illness. The inflammation passes from one joint to another so rapidly that some have considered it an example of metastasis. As a rule, however, the second series of joints are attacked before the first are entirely normal. Pitting on pressure occurs in some delicate patients. Suppuration is a very rare sequence in rheumatism.

The presence of excessive perspirations is a very frequent symptom. They occur in exacerbations, when the sweat often possesses a peculiar, sour odor. This is due to the presence of an acrid substance rather than to excess of lactic acid. A red, papular eruption, together with sudamina, frequently appears on the skin, the result of profuse sweating.

A peculiar erythematous eruption, peliosis rheumatica, has been noticed in some cases of acute rheumatism. The rash does not differ from erythema multiforme, as we now use that term. Urticaria is present in some cases. The temperature during an attack rises to 102° or 104° F.; in some cases of hyperpyrexia it rises to 110° F. The fever is of a remittent rather than a continuous character. The temperature is usually higher in proportion to the number of joints attacked. The tongue is coated thickly with a white fur. The saliva, which is normally alkaline, becomes acid. There is loss of appetite with more or less nausea. The bowels are constipated. The urine is scanty, high-colored, and strongly acid in reaction; its specific gravity is higher, owing to increased quantity of urates and urea; on standing a reddish sediment is formed. Albumen is sometimes found in small quantity during the febrile stage and during convalescence. The pulse is increased in frequency, often out of proportion to the rise in temperature. This may be due to severe pain or to the onset of cardiac trouble. The respirations are frequent and often shallow. They become greatly hurried when there are severe heart-complications. The red corpuscles of the blood are much decreased in number, and the amount of fibrin is increased.

In a large proportion of cases, the fibro-serous structure of the heart is attacked. The endocardium is much more frequently affected than the pericardium, the proportion being as six to one. In a few cases the muscular wall is also involved. The structures are attacked in the same way as the joints, the result of the elective affinity of the poison. Their involvement is not an instance of metastasis, nor should it be regarded as a complication, but simply as a part, of the disease. Rheumatic inflammation of these structures differs from that of the joints in two or three particulars. The exudation contains lymph, often becomes organized, and occasionally degenerates into pus. Pericarditis is usually accompanied by a dull pain beneath the sternum and a sense of oppression in the chest. By auscultation a friction-sound can be heard most distinctly over the base of the heart. This soon disappears as the serum accumulates in the pericardial sac. The presence of the latter is diagnosed by the increased cardiac dulness and diminished cardiac impulse. The endocardial inflammation is confined almost altogether to the left side of the heart. Its presence is usually made known by abnormal valvular murmurs, which are heard on auscultation. It may here be stated that one often hears abnormal heart-murmurs, during an attack of rheumatism, which disappear in a few days. In some of these cases it is difficult to say whether endocarditis was present or not. Two theories have been given to explain such cases: First, that there is a temporary dilatation of the heart; second, that an endocarditis may exist which undergoes rapid resolution. For further details, see vol. iii., pp. 583 and 584; and vol. v., p. 573 et seq.

The duration of acute rheumatism varies much—it may disappear in five or six days, or it may last as many weeks. The average duration is from two to three weeks. The patient is scarcely ever free from pain and fever during this period, and there are frequently exacerbations, which are followed by periods of comparative relief. There is a strong tendency to relapse, and many patients are subject to repeated attacks of the disease.

Unusual Events and Complications in the Course of Acute Rheumatism.—A frequent complication is pleurisy of the left side, which is said to occur in ten per cent. of all cases in which the heart is involved. Bronchitis, congestion, œdema of the lungs, and catarrhal pneumonia are sometimes concurrent with acute rheumatism. In rare cases inflammation of the meninges of the cord and brain complicates the disease.

Delirium, convulsions, and coma have been recorded. Chorea sometimes follows rheumatism in children. Acute delirium occurs in cases of hyperpyrexia. Organic changes of the nerve-centres from embolism are among the possibilities. A few singular cases of rheumatic hyperpyrexia have been recorded by Ringer, Maclagan, and others. In these the temperature rises sometimes to 110°. They are marked by the presence of acute delirium, which rapidly passes into coma; such cases are very frequently fatal. They often commence and continue for a few days in the ordinary way, when suddenly the temperature rises and the patient becomes delirious. It has been found necessary to reduce the temperature by the application of ice, and some cases have been saved in that way. It is probable that the excessively high temperature is due to impairment of the heat-centre in the bulb, and the brain-symptoms result from the effect of heat upon the nerve-substance.

Subacute Rheumatism.—Under this head cases have been described in which only two or three of the joints are affected at one time, and the pyrexia is of a mild type, the temperature not rising above 100° F. The duration is usually much longer than in the acute cases, but the joints are not permanently affected and serious heart-trouble does not follow. This subacute variety forms a connecting link between the acute and chronic forms. In a few cases the disease, after attacking two or three joints, finally settles in one articulation. This is usually the case in the gonorrhœal form, but it also occurs sometimes in the acute and subacute varieties.

Etiology.—Exposure to dampness and cold has generally been considered the principal factor in the causation of rheumatism. Severe muscular exertion, attended by overheating of the system and followed by chilling of the surface, is a frequent cause. Neither of these will produce rheumatism unless the patient is predisposed to the disease, either from hereditary or acquired taint. An hereditary predisposition, according to Fuller, is present in thirty-four per cent. of all cases. A long residence in a damp and cold climate seems to render the system liable to an attack. Age has a strong influence in predisposing to rheumatism. It does not often attack children under fifteen years of age, nor adults over forty-five. One is more subject to it between the ages of fifteen and thirty than at any other time of life. The heart is not often attacked after forty years of age. The same person may suffer from several attacks. The number of males affected is somewhat larger than the number of females. The former are more exposed and more frequently engaged in severe muscular exercise. Season and climate exert a predisposing influence. It is most prevalent in the cold, moist climate of the temperate zone. On this continent most cases occur in the latter part of the winter or early spring. Occupations which require great muscular effort in a warm atmosphere predispose to rheumatism. Washerwomen, bakers, maid-servants, moulders, and laborers generally are among those especially liable to the disease. Diet probably exerts some influence; the ingestion of an excessive amount of saccharine and starchy food increases the tendency to this malady. Certain diseases appear to have an etiological relationship. In the desquamative stage of scarlet fever, a mild form of articular inflammation sometimes presents itself. In dengue, hæmophilia, gonorrhœa, and in the puerperal state, a special tendency to inflammation of the joints appears to be present. In some of these latter diseases the polyarthritis is often of a pyæmic form.

Pathology.—Rheumatism must be considered as a general disease with local manifestations. The febrile condition appears to be a primary rather than a secondary element in the process. The inflammatory condition is

of a special character, and is the result of a materies morbi existing in the blood. It has a tendency to attack the fibro-serous structures connected with the locomotor apparatus and with the heart—in other words, those structures subject to movement and strain. As to the nature of the materies morbi, there has been much difference of opinion. According to Prout's theory, laçtic acid is the foreign constituent of the blood which causes the local inflammation. The arguments in favor of this view may be briefly stated as follows: First, that in acute rheumatism we always have an excess of the acid; second, that in some cases of diabetes, where lactic acid had been given for a few weeks, symptoms of rheumatism were developed; third, that the injection of lactic acid into the blood of lower animals has resulted in the production of endocarditis. The malarial theory has been strongly advocated by Dr. MacLagan. He is of the opinion that the excess of lactic acid is the result rather than the cause of the rheumatic process, and that the essential cause of the disease is a miasm which enters the system from without. He finds strong confirmation of his theory in comparing rheumatism with remittent and intermittent fever. According to this view, the salicylates act by destroying the malarial poison, and thus check the disease at its commencement.

Hueter is of the opinion that the micrococci pass into the blood through the sweat-glands, and first set up endocarditis. From this source emboli pass into the general circulation.

The nerve theory, which was first promulgated by Dr. I. K. Mitchell, and afterward supported by such eminent clinical authorities as Gull, Weir Mitchell, Charcot, and Jonathan Hutchinson, has received much attention. According to this theory the exciting causes, cold or dampness, produce an impression on the surface of the body which is conducted to the vaso-motor and trophic centres by the afferent nerves. The joints and other structures become affected through these systems. One would suppose, if this were the correct view, that the disease would come on much more quickly after exposure than is really the case. By combining these various theories we may, perhaps, arrive at a fairly correct view of the nature of rheumatism. This special form of inflammation is the result of the presence of abnormal products in the blood, of which lactic acid appears to be the most prominent. Their existence may be due to several causes. One of these may be the entrance into the blood of a special micro-organism, as taught by Recklinghausen and Klebs. Another cause may be an hereditary condition of the system, in which there is deficient power of assimilation. Prolonged exposure to a damp, cold atmosphere may produce the same result. It is a singular fact that prolonged and severe muscular exertion should so often light up the disease. In such cases it is probable that, previous to the exertion, the system contained all the abnormal products possible, and that the sarco-lactic acid evolved during exertion was just sufficient to turn the scale.

Prognosis.—The prognosis of rheumatism is favorable, so far as the immediate result is concerned. Death rarely takes place during the acute attack, unless there are serious complications. The pathological changes which sometimes take place in the heart structures are often the cause of death at a later period. When a case of acute rheumatism terminates fatally, it is usually the result of severe heart trouble. In such cases the cardiac walls are often affected. The prognosis is also favorable, so far as the joints are concerned. Permanent changes in the articulations are rare, unless the disease becomes chronic.

Treatment.—The therapeutics of rheumatism is still in an unsatisfactory state, as may be inferred from the number of remedies recommended. For years the alkaline treatment, as taught by Fuller, was very largely adopted. According to this method the bicarbonate of potash or soda was given in large and frequently repeated doses, until the urine became alkaline or neutral in reaction. This can be accomplished in from twelve to twenty-four hours. Fuller gave sodium bicarbonate, one and a half drachm; potassium acetate, one-half drachm, in three ounces of water, to which half a drachm of citric acid was added just before administration. This dose was repeated every three or four hours until the urine became alkaline. As a rule, in general practice the alkalies are not given in such large doses, nor so frequently repeated. This may explain, as Dr. Howard suggests, the difference in the recorded results. The theory upon which this treatment is based is, that by the administration of alkalies we counteract the acid condition of the blood and of the secretions. It has been proved that by this method we are enabled to mitigate the severe pain of rheumatism, but it is doubtful if by it the duration of the disease has been shortened or heart complication prevented. Drs. Gull and Rees published a number of cases, thirty-five in all, in which the expectant plan had been adopted. No specific remedy was administered. The average duration of the acute symptoms, when the heart was not involved, was a little over eight days; when the heart was affected, the duration was about twenty-two days.

Other remedies, such as quinine, tincture of iron, colchicum, propylamine, and lemon-juice have been recommended from time to time.

Salicin.—Dr. MacLagan, in 1876, published, in the London *Lancet*, his experience in the administration of salicin in acute rheumatism. He commenced to use it in 1874, and was so struck with the decidedly good results obtained that he spoke of the remedy with great confidence.

About the same time Kolbe, in Germany, discovered a method of obtaining salicylic acid from carbolic acid. This drug was used in rheumatism by Stricker and Riess with much success. An account of their experience was published in the early part of 1876. The appearance of these papers marked an era in the treatment of rheumatism. Salicin and the salicylates have since been largely employed, and we are now in a fair position to judge of the results. The latter may be epitomized as follows: (1) The salicyl compounds have a decided action in mitigating the severe symptoms when they are administered early and in frequently repeated doses; (2) the average duration of the disease has been shortened by these remedies; (3) they do not prevent heart complication; (4) relapses occur more frequently when the salicyl treatment has been used. It has also been asserted that patients do not rally so quickly after they have taken these drugs. Dr. MacLagan recommended salicin to be given in from twenty to forty grain doses every hour at the commencement of the attack.' Salicylic acid may be administered in twenty-grain doses every hour until the urgent symptoms are relieved. It is now usually given in combination with soda, in the form of sodium salicylate. It is necessary to continue the salicylate during convalescence to prevent relapses. One great drawback to the use of the salicylates is their irritant action on the stomach. This is much relieved when a simple solution is taken in aerated water. Weakness of the heart's action has been noticed after large and repeated doses. This has been so marked in some cases as to require the use of stimulants. A buzzing sound in the ears and temporary deafness are almost universally experienced after the use of the salicyl compounds. Dr. Howard, of Montreal, recommends the administration of citrate of potassium in combination with sodium salicylate. He also recommends benzoate of ammonia in cases where the salicyl compounds have failed. Latham recommends the salicylic acid made from salicin as a better preparation than that made from carbolic acid. Oil of gaultheria has been recommended by Dr. Kinnicutt, of New York, who used it in a number of cases instead of sodium salicylate. It is composed of ninety per cent. of methyl salicylate, and ten per cent. of terebine. Ten to fifteen minims are given floating on milk, or dropped on loaf-sugar. The effects are very similar to those of the other salicyl compounds. In the later stages quinine is indicated in moderate doses. Dr. Bartholow gives the following excellent rules for treatment. He divides cases of acute rheumatism into three classes: (1) In fleshy persons, those, for instance,

who drink beer to excess, the disease is generally subacute and lengthened in character. In these, alkaline treatment, as given by Fuller, is of the most service. (2) In ordinary cases of the acute disease in a previously healthy subject the salicyl compounds are the proper remedies. (3) In anæmic cases tincture of iron in large and repeated doses will have the best effect. In these latter cases the salicyl compounds are more likely to produce weakness of the heart's action than in strong persons.

Local Treatment.—Wrapping the affected joints in cotton batting is usually the only local treatment adopted. Dr. Herbert Davies, of London, recommends the application of blisters over the swollen articulations. These seemed to reduce rapidly the local inflammation, but the frequent production of strangury was a decided drawback to the treatment. Tincture of iodine has been recommended as a local application. Belladonna liniment with a solution of opium is often of service in relieving pain. Fuller's lotion consists of Battley's solution of opium (an English preparation), ℥ j.; potassium carbonate, ℥ ss.; glycerine, ℥ ij.; water, ℥ vj. It may be freely applied. As rheumatism is a general rather than a local disease, its successful treatment will depend rather on internal than external remedies.

General Measures.—The patient should be placed in a well-ventilated room. The temperature should be moderate and constant. The clothing ought not to be so heavy as to increase the perspiration. The body should be frequently rubbed with a dry towel, so as to remove the excessive perspiration. A light, unstimulating diet is the safest during the acute stage. Tonics and good diet are indicated in the stage of convalescence. Stimulants are rarely needed. *James E. Graham.*

RHEUMATISM, CHRONIC ARTICULAR. Syn.: Arthritis Rheumatica Chronica, Rheumarthritis Chronica. Chronic articular rheumatism is a mild but persistent inflammation affecting the ligaments, synovial membranes, cartilages, and sometimes the capsules of the joints. It may be limited to any one of these structures, or it may pervade them all at the same time. It may be limited to the structures of a single articulation, but more frequently it affects several simultaneously or in quick succession, more especially the smaller joints of the extremities.

Morbid Anatomy.—The morbid actions constituting chronic rheumatism, affecting the fibrous structures connected with the articulations, pretty uniformly induce more or less plastic exudation or proliferation and thickening of the parts, but with no tendency to purulent degeneration or formation of pus. In cases of long standing the thickened and dense ligaments often coalesce with the softer tissues; the villi in the interior of the joints become hypertrophied, and the cartilages become uneven and undergo some fatty changes, causing the whole joint to appear enlarged, altered in shape, and much less movable than natural. When the synovial membranes are involved, a small quantity of turbid serous fluid is often found in them, which is generally much increased temporarily by occasional subacute attacks, to which such cases are very liable from sudden and severe atmospheric changes.

Etiology.—Chronic articular rheumatism is often the sequel of more acute attacks; but many cases are chronic *ab initio*, and are of particularly frequent occurrence in cold, damp, and variable climates, and among such adults as are much exposed to cold and wet in connection with severe physical exercise. Living or working in cold and damp rooms or workshops, or standing with the feet and hands much in water, actively dispose to attacks of chronic rheumatism, more especially in the smaller articulations of the upper and lower extremities, and in the lumbar region of the spine. Consequently, washerwomen, housemaids who do much scrubbing, and coachmen or those who wash carriages, are particularly liable to this form of disease. But cases are occasionally met with in all classes, and in those engaged in any of the various occupations, although the disease occurs very rarely in childhood or youth.

Symptoms.—When chronic articular rheumatism is the sequel of acute attacks, the affected joints remain slightly swollen, with stiffness and some soreness on motion, which is usually diminished by continuous moderate exercise, but returns again after a few hours of rest. There is no redness of the surface nor increased heat, and generally but slight tenderness to the touch, except when the disease is aggravated by the supervention of more acute symptoms from fresh exposure to the primary causes. At such times the dull, aching pain is increased, especially during the night; there are moderate general febrile symptoms, and some serous effusion into such synovial sacs as are involved in the inflammation. In a few days these more active symptoms subside, leaving only the usual local stiffness and dull pains that belong to all cases of chronic rheumatism, whether preceded by acute attacks or not. In nearly all cases the pain in the affected part increases during the middle and latter part of the night, and is less during the day. Still more marked increase of the pains accompanies almost every change in the atmosphere in the direction of cold and wet. So true is this that many rheumatic patients detect the developing atmospheric changes earlier than are indicated by either barometer or thermometer. In some rare cases, in which the ligaments and tendons become not only indurated but closely adherent to their sheaths and to the soft parts surrounding them, all motion is interrupted, constituting a form of anchylosis.

A few cases of this kind have come under my observation, in which the knees, ankles, and smaller joints of the feet, together with the elbows, wrists, and articulations of the hands and fingers had become fixed at different degrees of flexion, thereby rendering the patients unable to get either the hand to the head or both feet on the floor at the same time. The most common and constant symptoms of chronic articular rheumatism are dull pains in the affected parts during the night, especially during the transition seasons, when frequent atmospheric changes occur; and stiffness with some pain on rising from the bed in the morning, which diminishes or disappears by moderate exercise during the morning hours.

In a large proportion of cases the general health of the patient is good, and all the important functions are performed with regularity. In many, however, the skin is more dry, the urine is scanty and high-colored, the bowels are habitually costive, and there are acid eructations or flatulency.

Diagnosis.—To distinguish chronic rheumatic arthritis from traumatic, scrofulous, or nervous affections of the joints, is not generally difficult. The dull character of the pain, its proneness to increase at night, and to be greatly influenced by atmospheric changes; the greater stiffness and soreness on motion after rest, diminishing with exercise; the middle or advanced period of life, and the entire absence of any tendency to suppuration, are so characteristic of chronic rheumatism, and so nearly the reverse of what occurs in the history of other affections of the joints, that few mistakes need be made unless through carelessness or want of attention to all the facts and circumstances of each case.

Prognosis.—This, so far as relates to the continuance of life, is always favorable in this disease, but almost equally unfavorable so far as regards complete and permanent recovery. In some comparatively recent cases I have seen permanent recoveries, usually, however, in consequence of removal to a more favorable climate; and, in a large majority of cases, much relief or mitigation of the disease has been obtained by proper and persistent attention to such prophylactic measures as are available.

Treatment.—As just intimated, the successful management of cases of well-established chronic rheumatic arthritis is a task of great difficulty. This is owing largely to the fact that much the larger number of these cases occur among the laboring classes, and in individuals who can neither afford to separate themselves from further exposure to the predisposing and exciting causes of the disease, nor be induced to adopt such measures, habitually, as would best protect them from the effects of the further exposures. These patients gener-

ally call for the aid of their physician only when they are suffering from an exacerbation of their symptoms, and cease to heed his directions as soon as the more active symptoms have subsided. When called to such cases, I have found no remedies for internal use more beneficial than the salicylate of sodium, or acetate of potassium, in solution with either the fluid extract or tincture of phytolacca decandra, cimicifuga racemosa, or senecio aureus and stramonium. The following is a convenient and efficient formula:

℞. Salicylate of sodium...25 grams = ʒ vj.
Fl. ext. phytolacca dec....60 c.c. = ℥ ij.
Tinct. of stramonium.....15 c.c. = ʒ iv.
Simple elixir.............75 c.c. = ℥ ijss.

Mix, and give four cubic centimetres (ʒ j.), in a little sweetened water, every four or six hours, until the more active symptoms are relieved. If the bowels should be irritable or too loose, the cimicifuga or senecio may be substituted in place of the phytolacca in the same proportion to the other ingredients. If the fresh aggravation of symptoms has been sufficiently severe to cause some increase of temperature, with dry skin and white coat upon the tongue, early and more certain relief may be obtained by giving, in addition to the other remedies, five or six decigrams (gr. viij. or x.) of Dover's powder and two decigrams (gr. iij.) of calomel at night, followed by a saline laxative in the morning. For permanent relief or palliation of chronic arthritis it is necessary to maintain, as far as possible, a healthy and natural action of all those organs and functions concerned in the work of eliminating the products of tissue-changes, and other waste and foreign material, from the blood. The best means for doing this are chiefly hygienic rather than medicinal. To lessen the effects of sudden and extreme atmospheric changes, underclothes of flannel or other non-conductor of heat and electricity should be habitually worn next to the skin; damp and cold rooms should be avoided; both physical and mental exercise should be as uniform as possible, extremes in either direction being avoided; the diet should be plain, nutritious, and sufficient in quantity and variety to furnish all the elements for healthy nutrition; and the drinks should be such as do not retard molecular changes in the blood and tissues, nor lessen important excretory functions. Good water, milk in any form, and tea and coffee of moderate strength, may be used *ad libitum;* but all forms of alcoholic drinks, whether fermented or distilled, lessen molecular changes and the elimination of excretory material, and favor the accumulation of such material in the blood and tissues, and therefore should be entirely avoided. In addition to all these ordinary hygienic measures, the use of a warm alkaline bath, followed by light, rapid friction with dry flannel, once or twice a week, has been found of much service in cases characterized by habitually dry skin and high-colored urine. The best time for the bath is just before retiring to bed in the evening. In cases where the circumstances of the patient will permit, a permanent change of residence from a cold, damp, and variable climate to one that is mild and dry, will be the surest mode of obtaining permanent relief. The use of mineral waters containing an excess of alkaline carbonates, both for drinking and bathing, also proves beneficial in many cases.

Strict attention should be given, in all cases, to the keeping of the digestive organs and the secretory functions generally in as healthy a condition as possible. Thus far I have said nothing regarding local applications to the affected joints. In comparatively recent cases, and in temporary exacerbations of old cases, painting the affected parts with tincture of iodine until the skin becomes tender will do some good; or a cautious application of oleate of mercury and morphine may be made morning and evening, for two or three days, and be followed by a liniment containing camphorated soap liniment, 260 grams (℥ viij.,) and menthol, 6 grams (ʒ jss.); this may be applied two or three times a day.

A great variety of local applications, including gentle and continuous currents of electricity, have been devised and recommended by different writers and teachers; but experience has demonstrated their effects to be either useless, or only temporarily beneficial. Chronic rheumatic arthritis is liable to be complicated with gonorrhœal, syphilitic, and gouty constitutional conditions of the patient. Of course, in such cases the treatment must be varied to meet the indications afforded by these complications.

N. S. Davis.

RHEUMATISM, GONORRHŒAL. This is an arthritis, rheumatoid in character, involving a single joint, or at most only a few joints, and in those first attacked generally persisting in a chronic manner for a number of days or weeks; rarely or never suppurating; with never serious, and sometimes no, constitutional disturbance; usually on subsidence leaving some thickening and stiffness of the joints, which may endure for months or permanently; depending on some irritation of the mucous membranes of the genital or the genito-urinary canal, usually gonorrhœal in character. It has no relation with ordinary rheumatism, and the name gonorrhœal rheumatism is misleading. A better name is *urethral arthritis.* Writers on the subject show, by lack of uniformity in descriptions of the disease, as it occurs typically, that they are not entirely agreed as to where to draw the line between this and other rheumatoid affections.

ETIOLOGY.—The disease attacks individuals of any age from puberty up to fifty years. The greater number of patients are men—less than seven per cent. being women. Neither seasons nor temperature particularly influence its occurrence or course; nor does atmospheric humidity or the state of the barometer. Rheumatic subjects are not more prone than others to acquire it; the claim has been made, probably on insufficient grounds, that they are less so, and that a rheumatic diathesis is protective against this affection. A lowered condition of the system, bad surroundings, cold-catching, and exposure, seem to have no direct influence in producing it. Almost without exception it follows urethral or vaginal irritation or inflammation of some description. Nearly always the irritation is gonorrhœal; probably the exceptions do not aggregate one per cent. of the cases, and many of the cases recorded as exceptions are open to challenge. Arthritis occurs occasionally in cases of simple inflammation of the urethra due to passing the sound or catheter, or to the treatment of a stricture, but in such cases it will usually be found that gonorrhœa had previously existed, if not arthritis also. It is one of the rarest clinical observations to see an arthritis resembling this disease follow a non-specific urethritis or vaginitis in a person who never had gonorrhœa. One attack of gonorrhœal rheumatism rather predisposes to another, and in the same joints. A patient may have several successive attacks, each following promptly upon a fresh gonorrhœa, and each involving the same articulations. It has been claimed that irritation of the posterior portion of the urethra must be more prone to produce arthritis, since the affection is never observed in the early days of a gonorrhœa, or when only the anterior portion of the urethra is involved, and since it is less likely to follow a first attack of gonorrhœa than a subsequent one, when the posterior part may be expected to be most affected. Apparent recovery often fails to remove all the products of the inflammation of the joints; some thickening of the tissues about the articulation is usually left, which may itself be the element that invites a fresh attack.

Arthritis follows only a small proportion of cases of gonorrhœa, probably not over two per centum.

Besides the poison and the irritating effects of the urethritis, a positive personal predisposition seems to be required for the occurrence of the rheumatoid affection. The joint inflammation rarely follows promptly the outbreak of urethritis; usually a few days, sometimes several weeks, intervene between them. Statistics that seem reliable appear to show that about sixty per cent. of the cases occur in the third and fourth weeks of the gonorrhœa. The arthritis may come on just as the gonorrhœa is fading away, but usually some change is noticeable in the symptoms of the latter, some aggravation often, before the former occurs. Mild cases of

gonorrhœa are nearly or quite as likely to lead to urethral arthritis as are severe ones.

Several theories of the etiology of this disease have been brought forward, but no one of them is proven. One is that a poison which is characteristic of gonorrhœa —possibly a micro-organism, the gonococcus, or some other—is actually absorbed or taken up from the mucous membrane, and, infecting the system, falls with most force on the parts of greatest susceptibility, which are the joints. It is even claimed that gonococci have been found in the products of the inflammation about the joints and in the blood. But this theory leaves unexplained the few well-authenticated cases of arthritis following non-specific urethritis; it is irrational to suppose in them the existence of such a poison as the theory requires. Another view is that the arthritis is a reflex phenomenon. Another holds that the inflammation extends from the mucous membrane to the sacral plexus of nerves and the spinal cord, and causes disturbance of trophic nerves, which in turn causes the arthritis, as this is produced in diseases of the spinal cord. This theory is as plausible as any. It makes the virus of gonorrhœa of no effect, except to cause an irritation—other irritants might do as well or as badly, and cause as many cases if they were as common. But the fact of the relative insusceptibility of women to the disease is left unexplained by all the theories.

Symptoms.—Gonorrhœal rheumatism usually begins a few days after the outbreak of the gonorrhœa that causes it, with mild febrile symptoms, and slight swelling with some pain and tenderness over one or more joints. Frequently at the beginning a number of joints are affected, the symptoms soon disappearing from all but one or two, where they remain often for weeks. The joints of the lower extremities are most frequently involved, and of these the ankle is much the oftenest affected. Next in frequency of attack is the knee, but the hips, shoulders, elbows, and wrists may be involved, as well as the joints of the hands and feet, the articulations of the jaws, the spine, and the pelvis. A majority of writers state that the knee is most often the seat of the disease, and, of the larger joints, the ankle the least often. Such statements must be based on personal observation in particular fields of practice. In the observations of the writer, in both hospital and private practice in Chicago, the ankle cases outnumber all others. One, or at most two, joints are usually all that become, or that continue, affected, and the arthritis continues in these—which are frequently the joints first attacked—till the end of the sickness, which is from two to twelve or more weeks in duration. In probably a fifth of all the cases the lesion is confined to a single joint.

The swelling, at first slight, increases gradually until it attains sometimes formidable proportions, and may thus remain for many days in spite of any and all treatment. The heat in the part is not great, nor is the tenderness usually, and the swelling, if it is discolored at all, has a dull redness quite in contrast with the appearance of an actively inflamed joint. The swelling and inflammation are evidently mostly of the tissues about the joint proper, since pressure of the articular surfaces against each other rarely causes pain. Any considerable motion of the limb or manipulation of the joint, however, causes pain, usually of a mild character, but sometimes severe and lasting long after its occasion has ceased.

As it occurs in the majority of cases, the general aspect and character of the arthritis stamp it as a process of a subacute and sluggish character. The signs and symptoms of intense and sthenic inflammation are wanting.

Usually there is but slight effusion into the joint. Hydrarthrosis occurs in a small minority of the cases, mostly of the knee, in some of which effusion is extreme, but in most it is slight. When dropsy of the joint does occur the inflammation of the tissues about the joint is relatively less severe, and the slight degree of the synovial inflammation is evidenced by the fact that aspiration of the fluid is often not followed by its reappearance.

There is, with the rarest exceptions, no destruction of the tissues of the joints, hence suppuration and ulceration of the synovial surfaces and structures are among the most infrequent occurrences.

As the affected joint slowly improves, the swelling abates, but it rarely disappears rapidly, and generally some stiffness of the articulation persists for a long time, or permanently. At times the effusion within and about the joint attains such a degree of consolidation that the joint is immobilized by a false anchylosis. A few cases are recorded where several, and one where nearly all, the joints of the body became fixed and motionless from successive attacks of this disease. In the cases of anchylosis moderate swelling remains about the joint, but the latter may become quite insensitive, and locomotion and bodily movements may be attended with the sole inconvenience resulting from the slight or complete abolition of motion in the articulations affected.

The constitutional symptoms of the disease, uncomplicated, are very rarely severe, and, after the first few days, may be absent. They embrace merely the evidences of a mild inflammatory fever, with its usual disturbances of the functions of the system, with anorexia, general pains, and restlessness. The temperature and pulse-rate are rarely high, and at the end of from three to seven days the system has usually resumed its normal conditions, except as to the local lesion. The general symptoms of ordinary acute rheumatism, such as continued fever, free perspiration, and excessive deposit of urates in the urine, are absent in this affection. Occasionally the arthritis is attended with more or less neuralgia, which may become extreme. The pain is sometimes most severe in cases attended with slight inflammation and swelling.

The occurrence of the arthritis does not influence the gonorrhœa, except during the first few days of fever. This condition may retard its recovery slightly; but as soon as the system resumes its normal condition, the gonorrhœa may improve, and pass on to recovery long before the joint affection. Indeed, in some cases the arthritis appears to exercise a decidedly beneficial influence on the gonorrhœa.

Complications and Peculiarities. — Urethral arthritis may be complicated by inflammation of the bursæ, the muscles, and the periosteum in the neighborhood of the swollen joints, by endocarditis, pericarditis, meningitis, myelitis, by adenitis, or by pyæmia. Ophthalmia occurs as a complication of the gonorrhœa by transmission of the poison to the conjunctivæ, rather than as a complication of the gonorrhœal rheumatism. The complications referred to are rare; the cardiac lesions being the most common. Probably more than four-fifths of all the cases of gonorrhœal rheumatism run the typical course already referred to without complications of any sort. Certain it is that heart lesions are not, in this disease, sufficiently frequent even to suggest any such predisposition in this direction as exists in ordinary acute rheumatism. As to the other lesions, whether they are complications of the gonorrhœa or of the rheumatism, is often uncertain. This is particularly the case with pyæmia, which may more rationally be supposed to arise from an inflamed urethra discharging quantities of pus, and perhaps being prodded by injection-tubes, if not worse instruments, and harassed with irritating medicines, than from arthritis, unless the joint be open to the air and suppurating.

Morbid Anatomy.—The usual lesion is a deposit of plastic material in the tissues about and of the joint. The failure of absorption of this is the common cause of the false anchylosis. Sometimes the effusion is into the joint-cavity. In these cases the synovial membrane is chiefly involved; in them the effusion may contain flakes of fibrine and leucocytes. Large effusions into the joints are very rare. Suppuration is extremely unusual, as is also erosion of the bony tissues. In exceptional cases the inflammation travels up the synovial sheaths.

Diagnosis.—This affection is liable to be confounded with a number of other diseases; among them acute rheumatism, chronic articular rheumatism, and the arthritis of pyæmia. From acute rheumatism it may be distinguished by the greater tendency in the latter to migra-

tion of the inflammation from joint to joint, by the greater intensity of the constitutional symptoms, and by the greater severity of the local pain and tenderness, as well as by the greater tendency to heart-lesion.

Chronic rheumatism may be confined to a single joint, or a few joints; but it very rarely causes such considerable swelling as is general in gonorrhœal rheumatism; and it nearly always fluctuates with changes in the barometric pressure, being worse on the approach of a storm—times of low barometer,—a behavior most unusual to urethral arthritis. The arthritis of pyæmia is most likely to be mistaken for this disease when the source of the infection is in the neighborhood of the urethra, when non-specific suppuration in the urethra, the prostate gland, the body of the penis, or some of the veins of these organs, has caused the pyæmia. But usually some of the characteristic general symptoms of pyæmia, and which are almost unknown in gonorrhœal rheumatism, make the diagnosis clear.

It must be borne in mind that true acute articular rheumatism may occur in the course of urethral arthritis.

Gonorrhœal rheumatism should be suspected, regardless of sex or condition, whenever, in a person of an age at which gonorrhœa is liable to be contracted, one or two joints become inflamed or swollen, without much serous effusion, showing little tendency to recovery, and pursuing the sluggish and peculiar course already described. It is not necessary to suppose every such person to have gonorrhœa; urethral or vaginal irritations not gonorrhœal, even other irritations, *may* cause the disease. But true gonorrhœa is found sometimes in unexpected quarters. It has more than once occurred to the writer, in hospital practice, to discover the true cause of what had been supposed to be an obstinate subacute rheumatism in the ankle of a young woman of supposed purity, in her confession of an irregular life and of having an irritating leucorrhœa and frequent, painful micturition. In all cases of arthritis that are not clearly of the character of ordinary rheumatism, inquiry should be made as to the condition of the urethra, both past and present, to ascertain whether there are any pus-discharging surfaces.

Prognosis.—The prognosis of an initial attack is favorable. Complete ultimate, albeit slow, recovery usually takes place, with some stiffness, however, remaining long after other evidences of the disease are gone. But each successive attack is more severe than the preceding, is more chronic, and more rebellious to treatment; and the danger of false anchylosis increases with the repetitions of the attacks. Persons are increasingly obnoxious to attacks of this disease with successive gonorrhœas, and after a gonorrhœa—especially if it has been followed by the arthritis—this affection is very liable to occur from any slight and non-specific urethral irritation, like that resulting from the touch of a catheter or sound, or even from urethral catarrh due to cold or any excess.

After a joint has remained swollen and stiff for six months, the prospect of its recovery is small, and any amelioration of its condition will generally be vexatiously slow.

The various complications make the prognosis more grave, in degree varying according to their character and severity.

Treatment.—The first step in the treatment is to cure the gonorrhœa. Often at the outbreak of the arthritis the gonorrhœa is insignificant; sometimes when severe at the moment of the appearance of the joint-trouble, it rapidly subsides if the constitutional symptoms are not marked. When it does not subside promptly, it should be treated as the first measure toward the betterment of the arthritis. There can be small expectation of any substantial improvement in the latter while the urethra is still inflamed. Not only should the gonorrhœa be cured as rapidly as possible, but all possible sources of irritation of the urethra should be removed; the urine should be rendered unirritating and be kept so; the diet must be unstimulating, large draughts of bland liquids must be drunk, and the bowels are to be kept open with cooling laxatives. Therapeutic measures are wanting to relieve directly many of the most obstinate cases of the arthritis; this will often, in spite of everything, drag along for months, but the substantial benefit that comes from removing all other irritations, and especially that of the genito-urinary system, is always within reach.

The acute symptoms of inflammation and fever may profitably be combated by the usual measures of anodynes for pain and discomfort—laxatives, low diet, quinine, hot fomentations, and, in cases of high temperature, antipyretics. This treatment is demanded alike for the comfort of the patient and for the possible abbreviation of this stage of the disease, although as to its great value in the last-named direction there is some doubt.

The post-acute stage, that in which the disease is confined to one or a few joints, may be treated with some advantage by the internal administration of alteratives—the iodide of potassium, biniodide or bichloride of mercury in moderate doses, and locally with rest, counter-irritants of croton-oil, tincture of iodine, frictions, and pressure, according to the needs of the case. Neither the salicylates nor any other of the so-called specific treatments for acute rheumatism have any special influence in this disease.

The course of many cases is extremely chronic, and often the practitioner is in doubt whether the most active treatment particularly hastens the recovery from the joint-affection. After the acute stage is fully passed the joint-thickening may be somewhat reduced by the systematic employment of massage. False anchylosis of long standing is remediless, except, perhaps, by breaking down by force the adhesions, and making and maintaining motion of the joint, a manœuvre that has been recommended.

Norman Bridge.

RHIGOLENE. Of the products of the fractional distillation of petroleum the lightest is obtainable as a fluid by condensation, and consists mainly of the paraffin *butane*, a body gaseous under ordinary conditions. This condensed distillate is termed *cymogene*. The distillate of next higher boiling-point boils at about 18° C. (64.4° F.). Such distillate consists largely of the fluid paraffin *pentane* ("amylic hydride"), C_5H_{12}, and is the substance commonly known as *rhigolene*. Rhigolene is a colorless, mobile fluid of slight and not unpleasant odor and taste; very light, very inflammable, and, as its boiling-point predicates, very volatile. It mixes in all proportions with common (ethylic) ether. Rhigolene was proposed by B. W. Richardson as a substitute for ether for the production of local anæsthesia by freezing, after his method. Because of the low boiling-point of rhigolene—lower than that of ether—the cold produced by the evaporation of a spray of rhigolene is very intense and very rapidly attained. Dr. Richardson has himself observed an area of skin become hard, white, and insensible at the expiration of *two seconds* after beginning the driving upon it of a rhigolene-spray. But such very rapid freezing Dr. Richardson finds undesirable, because the intense cooling of the superficial frozen area prevents the abstraction of heat from below, and so unduly limits the depth to which the anæsthesia can be carried. Hence Dr. Richardson prefers and proposes a mixture of rhigolene and anhydrous ether in equal parts. Rhigolene dissolves camphor, spermaceti, and iodine, and has been used by Richardson, again, as a solvent of those bodies for use for local applications. A rhigolene-solution of camphor and spermaceti together Richardson finds an excellent conjoint cooling anodyne and healing application to burns. The vapor of rhigolene, inhaled after the manner of vapor of chloroform, is readily taken, and produces general anæsthesia with great rapidity. But in this application rhigolene has shown itself dangerous, and has never come into practical use.

Edward Curtis.

RHINOSCLEROMA. Under this head Hebra described, in 1870, a disease seated in the nose, nasal passages, and pharynx, characterized by nodular swellings and infiltration of the affected parts, and a stony induration. As its name implies, the nose is the part most affected, and

the disease afterward involves the surrounding skin, the lips, and the mucous membrane of the mouth, the pharynx, and the larynx. It appears in the shape of smooth or nodular masses which are sometimes isolated, but generally merged into one another, so that the whole forms a connected mass. These nodules are very firm, slightly elastic, and sharply circumscribed from the surrounding healthy skin. The skin covering the growth is of a bright or dark red color, shiny, and contains many small blood-vessels, which form a visible net-work. It is perfectly smooth, and the hair- and gland-follicles are absent. The growth appears very similar to a keloid or hypertrophic scar, the skin having the same smooth, shiny character which is the result of the absence of hair-follicles and glands. As a rule, the growth first appears as a thickening and induration of the septum cutaneum, or of one of the alæ, without any inflammatory phenomena. After the disease has lasted many months the nose appears broader and flatter than normal, and the nostrils are rigid and dilated. On feeling the growth the peculiar hardness characteristic of it can be appreciated. The nose feels as

FIG. 3327.—Rhinoscleroma; case of Tanturi. (Copied from Schulthess.)

if it were cast in plaster of Paris, and the dilated nostrils cannot be closed. Hebra compares this induration with that of an initial syphilitic sclerosis, and says that the best idea of it can be obtained by supposing it to be one immense smooth chancre. It is not painful, except on pressure. In the course of time the disease advances in two ways. The most frequent course is along the nasal passages to the pharynx and palate. The nodular masses and induration extend backward, narrowing, and in some cases entirely closing, the nasal passages. The soft palate is attacked, becomes greatly thickened, and is frequently so deformed that it merely resembles a thick cord. Adhesions often form between the palate and the posterior wall of the pharynx, and deformities similar to those produced by extensive syphilitic ulceration and cicatrization may result. From its beginning in the nose the morbid process may extend to the upper lip and the mouth. The lips become nodular and thickened, and the orifice of the mouth may be so narrowed that operative procedures are necessary to enable the patient to take food. The gums and hard palate are more rarely affected. When this takes place the gums are swollen and indurated, the teeth become loosened and drop out, and the alveolar processes atrophy. From the mouth the disease may extend to the palate and pharynx, but in most cases infection follows from the other direction. The changes produced in the larynx are of great importance. The growth may involve the epiglottis and the mucous membrane of the larynx, producing fixation of the epiglottis, with aphonia, suffocation-phenomena, and epileptoid attacks. Catti has described a case in which the larynx was first attacked, and two years after this the characteristic growth in the nose appeared. In a case recently described by Schulthess, the disease appeared to have begun in the lachrymal duct, and made its first appearance as a nodule in the corner of the eye. After several years the nose, pharynx, and larynx became successively involved.

The growth advances very slowly. From its first appearance it often takes four or five years for the nodule to attain a superficial diameter of four or five centimetres ($1\frac{1}{2}$ to 2 inches), and cases are often seen which have lasted twenty years or more. In the case described by Schulthess the disease at the time of publication had lasted twenty-four years. Ten years had elapsed from its first appearance before the tumor-masses in the nose appeared, and the larynx became involved six years after this.

The absence of any tendency to suppuration and retrograde changes is one of the most striking features of the growth. Microscopically, the areas of fatty degeneration and coagulation necrosis, so common to most of the granulation-tumors, are not found. Even when it is cut into, and a piece excised, the wound quickly becomes covered with epidermis, and the part removed is soon replaced. On cutting into the tissue it is surprising with how much ease the knife enters it.

The subjective symptoms depend entirely upon the functional disturbances produced by the growth. The most prominent is the dyspnœa produced by the narrowing of the respiratory passages. The affection seems to exert absolutely no influence on the general constitution, independent of the functional disturbances spoken of. There is never any metastasis nor involvement of the lymphatic glands. The affected parts are never painful, except on pressure. Occasionally there may be a dacrocystitis, from an involvement of the lachrymal duct and a growth in the corner of the eye.

The first histological description of the disease was given by Kaposi, who studied some of the earlier cases published by Hebra. He describes the growth as a small-cell granulation-tumor, and regards it as a species of sarcoma. He denies that there is any transformation of the round cells into connective tissue, although he speaks of the cicatrization produced in the palate and elsewhere. Mikulicz, basing his conclusions upon a careful histological study, regards the entire process as chronic inflammation. According to him, a part of the round cells become changed into spindle-cells and connective tissue, which afterward undergoes cicatricial contraction. The microscopic study of the growth is best made by excising small pieces and hardening them in alcohol. Sections may then be made and stained with various reagents. Like most of the other granulation-tumors, the growth is principally composed of small round cells. Among these, sometimes lying singly, at other times in groups of two or three, are large cells which are more or less characteristic of the growth. In the older portions of the growth the round cells are pretty uniformly distributed throughout the tissue, but they are never so closely packed together as in most of the other granulation-tumors. The large cells have a protoplasmic net-work and contain two or three nuclei. They frequently contain round masses of a hyaline or colloid material, which stains with most of the aniline colors. A similar material is found in irregular masses scattered throughout the tissue between the cells. The cellular infiltration extends up to the epidermis, which is very thin, but which passes uninterruptedly over the growth. In places the epidermis sends down long projections into the tissue beneath. The glands generally atrophy and disappear, though in some cases, after closure of the ducts, small cysts are formed. In the younger portions of the growth the cellular infiltration is not so extensive, and is principally seen around the vessels. Bands of connective tissue with spindle-cells are

seen here and there, but the amount of connective tissue present is not so much as one would expect to find in view of the extraordinary hardness of the growth. In addition to these larger bands small masses of fibres are found here and there between the cells. The firmness of the tumor is principally due to the presence of the hyaline colloid material.

In 1882 Fritsch reported that he had found constantly in the rhinoscleroma short bacilli, which he was able to cultivate in aqueous humor. He made inoculations with the cultures, but did not get any results. From the constant presence of these bacteria he regarded them as causative of the disease. The best description of the bacteria is given by Cornil and Alvares, from whose drawings the accompanying figure is taken. The bacteria are principally found in the large protoplasmic masses which have been spoken of as characteristic of the disease. In addition, they are found in the interstices of the tissue and in the lymphatic vessels with which the tumor is abundantly supplied. They are short rods, and under low powers have more the appearance of micrococci than of bacilli. In the large cells they are in groups of from ten to twenty. In the lymphatics they are generally free. Cornil and Alvares described as characteristic of them small clear masses or capsules which surrounded them. Sometimes there is a constriction in the middle, giving the appearance of two bacilli enclosed in a single capsule. The capsule is best seen after staining with aniline water gentian violet, and then decolorizing with iodine. The bacteria present the most striking similarity to the Friedländer pneumonia-bacilli, and can be distinguished from these neither by their morphological

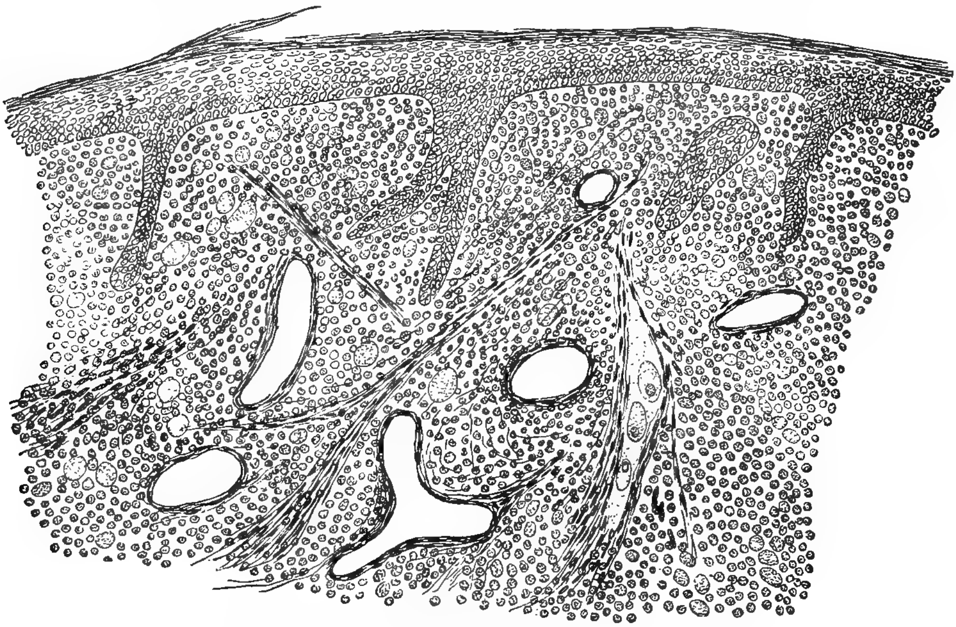

FIG. 3328.—Section through a Nodule of Rhinoscleroma. × 60.

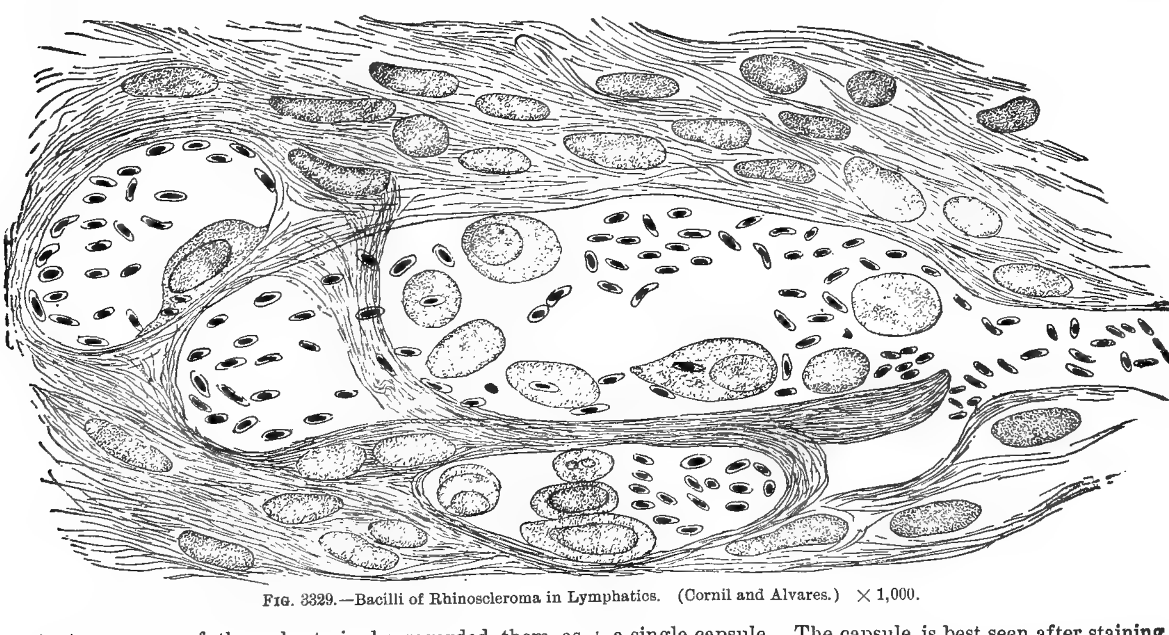

FIG. 3329.—Bacilli of Rhinoscleroma in Lymphatics. (Cornil and Alvares.) × 1,000.

characters nor by culture. They have recently been made the subject of careful study by Paltauf and Eiselberg. They made numerous inoculations in various animals, and succeeded in producing in mice the same changes that are produced by the pneumonia-bacilli. It is difficult to say with certainty whether or not these bacteria are the cause of the growth. They are invariably present, and their situation in the large cells and lymphatics shows that their presence is not an accidental one. Remarkable as is their resemblance to the Friedländer bacilli is, we are by no means justified in regarding them as identical. The very fact of the extreme rarity of the rhinoscleroma and the frequency with which Friedländer bacilli are found speaks against this view. In addition to this, the rhinoscleroma has a well-defined geographical distribution. Most of the cases have been found in Vienna, which may be regarded as the home of the disease. A few cases have been found elsewhere in Austria, a few in Italy, and one (that of Schulthess) in Switzerland. No cases have been met with in the United States, although several have been seen in Central America.

The diagnosis of the disease is comparatively easy. Hebra has given the following as the most marked characteristics: 1, The seat of the disease, which is in the nose or in parts immediately adjacent to it; 2, the peculiar hardness of the part affected; 3, the extremely slow development; 4, the sharp limitation of the growth, and the absence of œdema or of any inflammatory reaction in the surrounding tissues; 5, the absence of retrograde metamorphosis; 6, the inutility of all internal treatment; 7, the benign character of the growth as regards the organism, even when it has lasted years; 8, the absence of pain except on pressure. The only affections with which there is any probability of confounding it are syphilis and epithelioma. From the former it may be distinguished by its circumscribed growth, absence of ulceration, and the inutility of specific treatment; from the latter by absence of ulceration, its painless character, history of slow growth, and absence of infiltration of the surrounding tissue.

The treatment is confined to excision of parts of the growth, when it endangers life by closure of the nares, etc. No medication has been found to be of any avail, and by reason of the extent of the growth complete excision has not been found to be practicable. Frequent operations are necessary, as the portions removed are quickly reproduced.

W. T. Councilman.

RHINOSCOPY. Inspection of the nasal cavities and retro-pharynx is accomplished by two methods of examination. These are anterior rhinoscopy and posterior rhinoscopy.

Preliminary to the investigation of the nasal canals, it is well to observe the exterior of the nose. From the appearance of this, some suggestion may be obtained as to the existence of abnormalities within. Thus, deflection of the nasal septum is often attended with irregularity of external contour; the presence of an intra-nasal growth is attended with bulging of the alæ or distortion of the nasal bones, causing in extreme cases the appearance known as "frog face;" occlusion of the nasal passages and mouth-breathing are associated with the peculiar upturning and enlargement of the end of the nose, or, on the other hand, with the pinched, atrophied, and collapsed condition of the alæ commonly observed in such patients; chronic catarrh is attended with congestion and thickening of the alæ; and, finally, there may be actual depression of the bridge of the nose from surgical injury or from tertiary syphilis.

Although by no means infallible, the above are often useful guides toward a diagnosis. Again, the ease with which the exit of air is effected through one nostril, the question as to whether or not the patient can breathe for any length of time with the mouth closed, the existence of fetor in the expired breath, the quality of the voice, and the condition of the olfactory sense, are points of importance in the examination which are capable in many cases of conveying information, and which should not be neglected.

Inspection of a wide nostril may sometimes be partially accomplished by placing the patient opposite a strong light and then forcing upward the tip of the nose. This, however, is unsatisfactory. For the accomplishment of a thorough examination it is necessary to use, first, a good light; and, secondly, something in the way of a speculum by which the nostril can be dilated and the light thrown into the dark and remote passages which are to be examined.

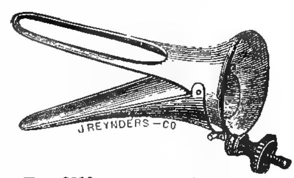

FIG. 3330.—Duplay's Speculum; modified.

Both anterior and posterior rhinoscopy may be efficiently performed by means of sunlight, and in some cases this is to be preferred. In most instances, however, the simplest and most convenient method will be by artificial light, and with the appliances used in the performance of laryngoscopy (see vol. iv., p. 385).

For the performance of anterior rhinoscopy many ingenious specula have been devised. Among the different kinds commonly sold by the instrument-makers, those pictured in the accompanying cuts (Figs. 3330 to 3332) will be found useful and convenient.

A very valuable form of nasal speculum is that of Sigmund, a tubular instrument made of hard rubber and shaped like an ear-speculum. It is particularly useful in the application of the galvano-cautery to the nasal cavities. An excellent substitute for a nasal speculum may be improvised from a common hair-pin by bending both ends of the pin in opposite directions, and thus forming a double curve, one end of which is held in the operator's hand and the other pressed outward against the ala of the nose.

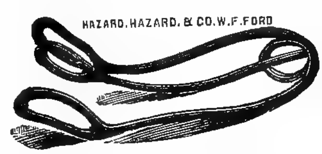

FIG. 3331.—Goodwillie's Speculum.

Among other good varieties may be mentioned Fraenkel's, Bosworth's, Creswell Baber's, and John N. Mackenzie's.

For the performance of anterior rhinoscopy the patient should be seated as for a laryngoscopic examination, and the arrangement of the light, the head, mirror, etc., should be the same as for the latter (see vol. iv., p. 386). The blades of the speculum should then be introduced into the vestibule of the nose and separated. The vestibule itself is lined with integument and furnished with an abundant growth of short, stiff hairs, which, for facilitating the examination, it is sometimes desirable to cut off. This, however, is seldom necessary. At the posterior superior limit of the vestibule is the opening of the anterior nares. Here the integument changes its character and becomes mucous membrane. Professor Wilhelm Meyer, of Copenhagen, has observed that in cases of chronic catarrhal disease the characteristics of the external integument are preserved to an unusual distance posteriorly.

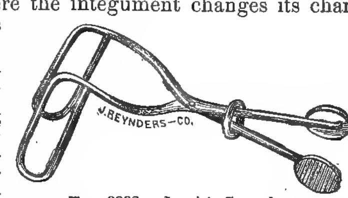

FIG. 3332.—Jarvis's Speculum.

Upon inspecting the nasal fossa, which is brought into view by the nasal speculum, the patient's head being bent somewhat forward, the first objects seen will be the anterior aspect of the inferior turbinated body and the lower part of the cartilaginous portion of the nasal septum. Beyond these may be seen the inferior meatus, the floor of the nose, and the lower border of the inferior turbinated body. Tilting the head a little backward, the remainder of the inferior and part of the middle turbinated bodies come into view. And, bending the head backward still farther, the uppermost part of the middle turbinated body and the roof of the nasal fossa can be seen.

The superior turbinated body may sometimes be demonstrated anteriorly, although this is unusual. Under inspection in the above positions, with the head turned a little to one side, the corresponding parts of the septum can be demonstrated.

The color of the nasal mucous membrane varies in different situations. The anterior and inferior border of the inferior turbinated body, and the floor of the fossa, are usually bright red, while the septum and the inferior border of the middle turbinated body are of a paler hue.

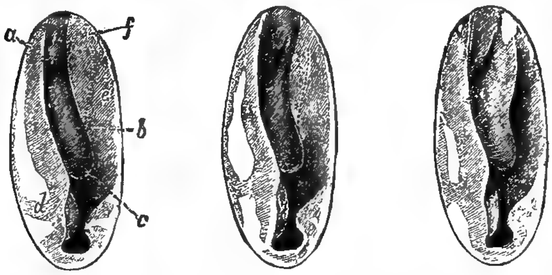

FIG. 3333.—*a*, Outer lip of anterior border of middle turbinated body; *b*, angle of middle turbinated body; *c*, lower border of middle turbinated body; *d*, inferior turbinated body; *e*, tubercle of septum; *f*, outer wall of nasal cavity. In diagrams A and B, the margins of the middle turbinated body, hidden by the tubercle of the septum, are indicated by dotted lines. (Cresswell Baber.)

The description of the contour of the parts seen by anterior rhinoscopy, and their recognition by one not accustomed to such examinations, are matters of considerable difficulty. They have been made much more clear and easy by the excellent work of Mr. Cresswell Baber, of Brighton, England, who, through a series of diagrams and illustrations, has sought to depict the real conditions normally present, and to assist the learner in understanding the variations in form which may occur in pathological states. The accompanying diagrams, while intended to illustrate the different appearances of the tubercle of the septum, convey an excellent idea of the neighboring parts.

As will be seen from these cuts, the extent of view obtained of the middle turbinated body will depend largely

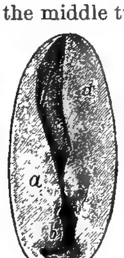

FIG. 3334.

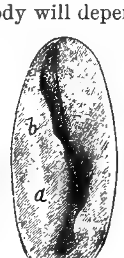

FIG. 3335.

FIGS. 3334 and 3335 represent respectively the right anterior rhinoscopic view of a man, aged twenty-four, before and after erection of the anterior end of the inferior turbinated body. (About twenty minutes elapsed between the times of drawing the two sketches.)

In Fig. 3334, *a* is the collapsed anterior end of the inferior turbinated body; *b* is the inner surface of ditto, which leaves a space between it and the septum, through which the palatal movement can be plainly seen. Above, the middle turbinated body *c* is visible, its neck being hidden by the tubercle *d*.

In Fig. 3335, *a* is the erected inferior turbinated body, terminating above in the swollen "neck" *b*, which almost entirely conceals the middle turbinated body. The upper parts of the drawing are slightly diagrammatic. (Cresswell Baber.)

upon the prominence of the tubercle of the septum. Undue prominence of this part may be reduced by the application of cocaine. When the erectile tissue of the anterior angle of the inferior turbinated body (*a*, Fig. 3335) is tumefied, this body appears as a rounded, shining eminence, having a smooth surface, which is in contact with or close to the nasal septum. Above, it is prolonged into a broad neck (Fig. 3335, *b*), the inner or free margin of which, if its erection be extreme, is in contact with the septum, and completely conceals the middle turbinated body.

When the soft parts lining the anterior aspect of the inferior turbinated body and the lower part of the septum are tumefied, or hypertrophied, the entrance of light to the nasal fossa will be greatly facilitated, as has been suggested before, by the use of cocaine. This drug, applied in a solution of from two to four per cent., will cause more or less complete retraction of the projecting tissues, and thus render possible a far more thorough and satisfactory inspection.

In the examination of the anterior nares, a short, delicate probe will give much assistance, as by its use the appearances conveyed to the eyes can be verified or disproved, the consistence of various parts fairly estimated, and, with the aid of a pledget of absorbent cotton, secretions which obscure the view may be removed. In all cases in which secretion exists, it must be recognized, and, if too great in amount to be dealt with in the way just alluded to, it should be removed by means of atomized spray or the ordinary nasal douche. Of the three methods the spray is likely to do the least injury, and is in a large proportion of cases the best.

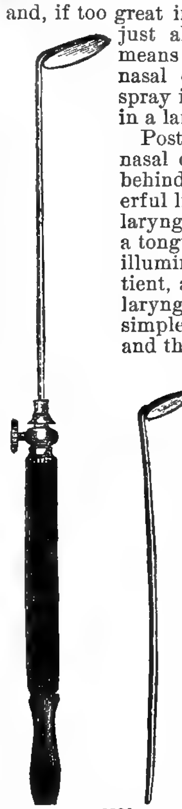

FIG. 3336.

Posterior rhinoscopy, or inspection of the nasal cavities and the upper pharynx from behind, is accomplished by means of a powerful light, a mirror similar to that used in laryngoscopy, only smaller in diameter, and a tongue-depressor. The conditions, as to the illumination and as to the position of the patient, are the same as for the performance of laryngoscopy (see vol. iv., page 386). The simplest and best form of rhinoscopic mirror, and the one in by far the most general use, is illustrated in Fig. 3336. As the reflecting surface is at best very small, and as in the use of the mirror much depends upon the perfection of its form in regard to certain details of shape and construction, it is important that the following points should be observed in selecting one: The reflecting surface should be perfect, the mirror itself as thin as can be made, and not more than one-sixteenth of an inch in thickness, while the metallic edge in which it is encased should encroach upon its reflecting surface as little as possible. Again, the shaft should be attached directly to the margin of the mirror, and not form an angle after leaving it; and finally, the shaft should be slightly flexible, so that, should occasion require, the angle at which it is set into the mirror may be altered.

Tongue-depressors are offered by the instrument-makers in great variety. These should be silver- or nickel-plated, and as free as possible from projections and irregularities of surface, so that absolute cleanliness may be easily secured. One of the most useful varieties ever devised is that invented many years ago by Türck. (For the use of the tongue-depressor and the examination of the lower pharynx, see vol. iv., page 387.)

For the performance of posterior rhinoscopy the patient should be placed in the laryngoscopic position, and a strong light should be thrown into the pharynx, the tongue being depressed. The rhinoscopic mirror, warmed to the temperature of 100° Fahrenheit, should be passed backward to the soft palate, behind which it should then be gently placed, care being taken not to provoke irritation by touching any of the adjacent parts. The positions necessary to a successful examination are well illustrated in Fig. 3337. The position of the velum palati should be such that the space between it and the posterior wall of the pharynx should be as wide as possible. In other words, the velum being perfectly re-

laxed, should hang well downward and forward. This may be accomplished by directing the patient to endeavor to breathe through the nose, the mouth being open, or by his pronouncing a purely nasal sound. The mirror having been introduced, the hand of the operator should be carried outward, so that the entrance of light to the pharynx may be unobstructed. By reason of the size and configuration of the upper pharynx, it is

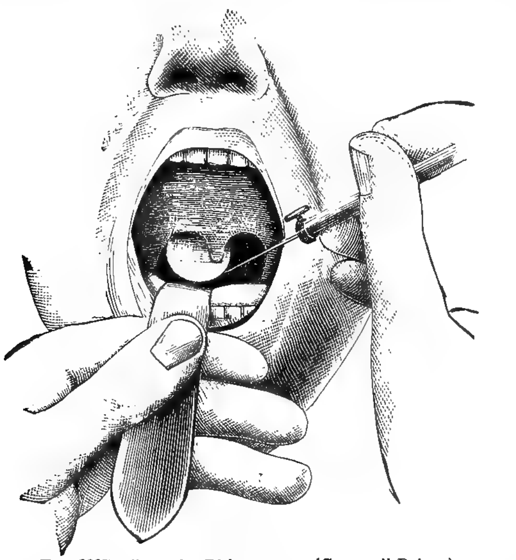

FIG. 3337.—Posterior Rhinoscopy. (Cresswell Baber.)

necessary to change the position of the mirror in order to demonstrate the whole cavity. The recognition of the different parts is somewhat difficult and confusing to the beginner, who will find it of great assistance to observe the following suggestions: In the first place, the normal anatomy of the region should be thoroughly understood. This may be easily acquired by studying the illustrations of the naso-pharynx in any standard work upon anatomy (see Fig. 3338). Upon introducing the rhinoscopic mirror, let the first endeavor be to demonstrate the vomer, which is not only the easiest object to bring within the field of the mirror and to recognize when seen, but, being in the median line, may serve as a point of departure for the rest of the examination; for,

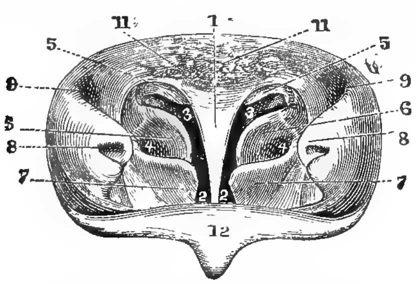

FIG. 3338.—The Rhinoscopic Image. 1, Vomer; 2, nasal passages: 3, superior meatus; 4, middle meatus; 5, superior turbinated bone; 6, middle turbinated bone; 7, inferior turbinated bone; 8, pharyngeal orifice of Eustachian tube; 9, upper portion of fossa of Rosenmüller; 11, glandular tissue at the vault of the pharynx; 12, posterior surface of the palate and uvula. (Cohen.)

starting with this and carrying the light upward, the roof of the nasal fossæ and the vault of the pharynx, with Luschka's tonsil, will come into view; while forward will be seen the posterior extremities of the three turbinated bodies, and outward the lateral wall of the pharynx, the orifice of the Eustachian tube, and the parts adjacent to it on the corresponding side.

In the examination of the upper pharynx certain difficulties may arise. Thus, the pharyngeal space may be unusually narrow, and the neighboring walls so thickened, congested, and coated with mucus, that it is impossible to gain a view of the regions above. Cleansing the mucous membrane and the application of a solution of cocaine, under such circumstances, will sometimes render a fair demonstration possible. The fact remains, however, that in certain infrequent instances the pharyngeal space is so reduced in size that an examination with the mirror is impossible, even in skilful hands. Yet such cases, it must be admitted, are sure to be less and less frequently met with as the experience and dexterity of the examiner become greater. Where examination with the mirror is impracticable, the method of palpation may be employed. Great caution and gentleness should be observed in its application.

An elongated and thickened uvula may offer a serious obstacle. Amputation of the redundant portion will render the examination easier.

Irritability of the pharynx may be overcome by the application of a solution of cocaine—two to four per cent.—or by the rapid drinking of ice-water, or the sucking of cracked ice.

Finally, it may sometimes be necessary to draw the velum palati forward by means of some form of instrument or device suitable for the purpose. Of the instruments which have been proposed, the most useful is a simple probe, covered with the material used in the English flexible, woven catheters. This seems less irritating than the unprotected metal.

Surgeon-General Wales, of the United States Navy, has devised the plan of passing a piece of tape backward through each nostril to the pharynx, and thence under the velum and forward, until the end is brought out of the mouth; the two ends of each tape are then tied together with sufficient tension to draw the velum well upward and forward. For operations in the upper pharynx this method, or some modification thereof, is very useful. *D. Bryson Delavan.*

RHUBARB (*Rheum*, U. S. Ph.; *Rhei Radix*, Br. Ph.; *Radix Rhei*, Ph. G.; *Rhubarbe de Chine, Rhubarbe de Muscovie, Rhubarbe de Perse*, Codex Med., etc.).

"The root of *Rheum officinale* Baillon, and of other undetermined species of *Rheum*, Order *Polygonaceæ*," U. S. Ph. "The root, more or less deprived of its bark, sliced, and dried, of *Rheum palmatum* Linn.; *Rheum officinale* Baillon, and probably other species. Collected and prepared in China and Thibet," Br. Ph.; of *R. officinale*, etc., Ph. G.; of *R. palmatum* Maxm.; *R. tanguticum* Linn.; *R. officinale* H. R. N., etc., Codex Med.

The sources of Asiatic Rhubarb, for they are undoubtedly several, are not known with anything like exactness, although upward of half a dozen have been designated by travellers and botanists. Most of these, upon examination of the structure of their roots grown in Europe, can be proved *not* to be the same as the commercial Rhubarb, but one or two may still be the same. The general features of the genus are familiar in the cultivated "Pie-plants," *R. Rhaponticum*, etc. They are large perennial herbs with very thick, fleshy roots, and immense leaves. The flowering stems, from four to ten feet high, are thick, hollow, more or less leafy and branching. Flowers small, numerous, green or whitish, sometimes pink or red. They have a six-parted perianth, nine stamens, and a three-cornered, one-ovuled superior ovary, with three recurved styles. The ovary is surrounded at its base by scales or glands. It develops into a three-angled, one-seeded achene. There are twenty or more species, all from Central and Southern Asia.

R. officinale Baillon. This fine, large species is one of the latest discovered, being made known through French missionaries in Thibet, in 1867. Specimens were sent about that time to Paris, where they have grown well, and from whence plants have been obtained for other gardens. It is quite hardy, grows freely, and produces a root that microscopically agrees with Asiatic Rhubarb. It is a large, handsome species, developing a thick, aerial, branching stem, several inches in diameter and a foot or

more long, tapering to a blunt apex, and covered with brown leaf-bases. It is internally fleshy and yellow, or orange. Roots also very large and thick. The lower leaves are very large, on long, cylindrical petioles, and form a pyramidal mass of foliage six or eight feet in diameter; their blades are roundish, heart-shaped, palmately veined, deeply lobed and serrate; the veins and petioles are very thick; under-surface pubescent. Flowering stems from five to eight feet high, much branched, terminating in numerous graceful, spike-like clusters of flowers.

R. palmatum Linn. has long been considered one of the sources of Rhubarb. It is also a very large herb. It has deeply lobed leaves on semi-cylindrical stems, and a rather close paniculate and compound inflorescence. It is a tenderer and more delicate plant than the preceding, and its root, at least as cultivated in Europe, does not correspond in structure with Asiatic Rhubarb (Flückiger). It is a native of Chinese Tartary. *Var. tanguticum*, according to M. Przewalski, is cultivated and collected in the place of that name in the Province of Kansu, of Northern China.

Fig. 3339.—Rheum Officinale. (Baillon.)

Besides the above, the following certainly do not produce genuine Rhubarb, although they have been considered to do so at one time or another. They are sources, however, of European Rhubarb, and are besides extensively cultivated in Europe and here for their pleasantly sour petioles, which by high cultivation and blanching grow very large and long.

R. Rhaponticum (Pie-plant) has semi-cylindrical petioles, and entire, wavy, heart-shaped leaves; *R. undulatum* has the upper side of the petiole concave, and sharply pointed leaves; *R. compactum* Linn. has serrated leaves; *R. australe* has round, broadly heart-shaped, rough leaves, etc.

All the above are from Central Asia, but they have been cultivated for a considerable time in Europe, either as "pie-plants" or on account of having some historical connection with the source of Rhubarb.

Of the varieties of Rhubarb there is but little useful to say, as they are often distinctions without a difference, since they are named, not from the species of Rheum, often not even from the places where they are collected, but from the towns or markets whence exported to Europe. "Turkey Rhubarb," exported through Asia Minor, has long since been obsolete; so is the so-called Turkey (Russian) Rhubarb of modern times. Both had their origin, like the present supply, in China or Thibet. Indian and Chinese Rhubarbs are spoken of now, but they have no essential differences, and are probably all Chinese in their origin. European Rhubarb (see below) is a distinct product, from *R. Rhaponticum*.

History.—Rhubarb has been used in China from the remotest ages (2700 B.C., Flückiger), and possible references to it are found in the earliest European books on medicine. As early as the seventh century of our era, there can be no doubt of its occurrence in Europe, and by the tenth or eleventh it was well known and highly valued. It was always, until recently, an expensive drug, on account of the long transportation required to bring it to market. One of the earliest routes was westward along the wastes of Central Asia, through the Caspian region to the Black Sea, or Asia Minor. It was long ago imported, too, by water from India as now, or rather around the Cape of Good Hope, and came in other ways, partly by land and partly by sea, through Persia or Egypt. For the past two hundred years traffic between China and Russia, through Siberia, has permitted this drug to be brought, by a long and painful route, to Europe through that country, terminating in Moscow. For about a hundred years previous to 1860 the Russian Government monopolized the Rhubarb trade between Siberia and the Chinese provinces, and established an exceedingly strict inspection of all the roots exported that way, condemning and destroying all but what was absolutely perfect. In this way an exceptionally fine quality was obtained, and exported, after its long hard journey, from Moscow. Curiously, in England and this country the old and entirely inappropriate name "Turkey Rhubarb" was given to this variety. Since 1860 this inspection has been discontinued, and this grade of Rhubarb has entirely disappeared from English and American commerce. The increased facilities of transportation from various Chinese ports, as well as from the whole of Asia, have also drawn the course of transportation southward.

Of the collection of Rhubarb but little detail is known. Several travellers have seen it in one district or another, and described it in general. The roots are dug, sometimes at least, in the fall, the larger ones and the root-stocks only being taken, and these are dried, according to some, by artificial heat; according to other reports, by the sun alone. That some pieces are strung upon cords to dry is evident enough; also that the roots are in some way deprived of their outer surface. The old Russian Rhubarb

showed the marks of the knife where it was peeled in good-sized slices, but the present Chinese pieces are all smooth and rounded, as if finely filed or scraped into shape after drying, or possibly smoothed by the attrition of long transportation.

DESCRIPTION.—Chinese Rhubarb is met with in pieces of various sizes and shapes, deprived of the cortical layer, having a smooth, rounded, and bright yellow-buff surface, evidently finally prepared after the root has dried. The most common form is cylindrical or barrel-shaped, as the roots, up to four or five centimetres in diameter, appear to be generally dried without splitting; larger than this they are cut longitudinally, and "flat Rhubarb" is the result. Besides these pretty uniform shapes, it is sometimes quite irregular. A small hole near one end, with its margins somewhat discolored, is usually present, and shows that the pieces are strung in rows to dry; bits of string are also frequently found in these perforations. Rhubarb is usually very clean and carefully sorted before it reaches us; even the different shapes and sizes are in some measure packed separately; here it is often again re-sorted, and the choicest-looking pieces are reserved for retailing whole, while the rest is ground, or it may be sawed in little cubes or prisms. The outer surface of regular pieces, where the bark is not too deeply cut away, shows numerous fine, deep orange, lozenge-shaped spots (the ends of the medullary rays), separated by a pretty regular net-work of white lines. These rays, in the interior of the root, are arranged with the greatest irregularity, generally in the cortical zone of the section, having a somewhat radiate tendency, but by no means always obviously. Near the cambium region is an irregular circle of small dark stars (as they appear in transverse section), about two millimetres in diameter, composed of short rays radiating from a point or short axis. Similar stars are seen more sparsely, also, in the interior parts of the root or stem. These stellate markings are only found on the larger pieces, the roots under two centimetres in diameter being wholly without them; but, when present, they serve to distinguish with certainty Chinese Rhubarb from the very much cheaper European sort. Rhubarb, to be of good quality, should be bright in color, glistening and brittle upon fracture, beautifully and clearly veined, and gritty when chewed. It has a bitter, very disagreeable astringent taste, and a peculiar, also disagreeable, aromatic odor.

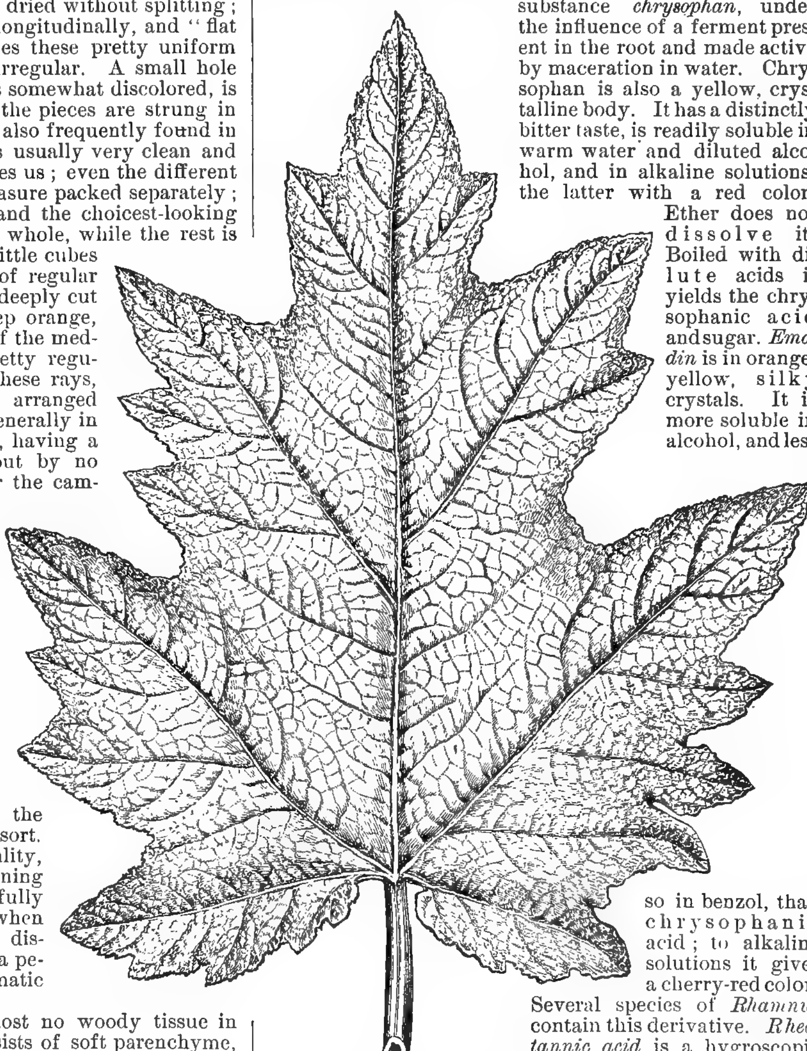

FIG. 3340.—Leaf of Rheum Palmatum; variety, tanguticum. (Baillon.)

COMPOSITION.—There is almost no woody tissue in Rhubarb. The white part consists of soft parenchyme, containing *starch* and crystals of *oxalate* of *lime;* the reddish lines and spots are medullary, and contain the active constituents and coloring matters. Both portions probably contain the mucilage, etc., of which the root has ten or fifteen per cent., as well as albuminoids, and other common plant-substances. No single constituent has been found in this root to represent all its activity, consequently no "active principle" of it is in the market, although one or two of the substances named below can be obtained of the chemists. Indeed, the composition of Rhubarb is still in many respects very obscure. The following list is quoted from M. I. Schmidt by Huseman, and bears date 1874: *Tannin*, 2.106 per cent.; *phæoretin*, 0.65; *chrysophan*, 0.05; *chrysophanic* acid, 4.70; emodin, 0.50; ash, 12.15. Of these one of the most important is *chrysophanic acid*. This is an orange-yellow compound, crystallizing in needles or six-sided prisms; it is without taste or smell, and can be partially sublimed. Cold water dissolves almost none of it; hot water dissolves a little, making a yellow solution. It is more soluble in alcohol, ether, etc., and in some acid and alkaline solutions. Chrysophanic acid is not peculiar to Rhubarb, but is also found in other species of *Rheum*, in the docks (*Rumex*), as well as in *Parmelia parietina* Ash, and other lichens. The chrysarobin of Goa is a related product. Although this acid is easily obtained from Rhubarb, according to Professor Kubli, it does not exist in the root, but is the result of a glucoside decomposition of the next substance *chrysophan*, under the influence of a ferment present in the root and made active by maceration in water. Chrysophan is also a yellow, crystalline body. It has a distinctly bitter taste, is readily soluble in warm water and diluted alcohol, and in alkaline solutions, the latter with a red color. Ether does not dissolve it. Boiled with dilute acids it yields the chrysophanic acid and sugar. *Emodin* is in orange-yellow, silky crystals. It is more soluble in alcohol, and less so in benzol, than chrysophanic acid; to alkaline solutions it gives a cherry-red color. Several species of *Rhamnus* contain this derivative. *Rheotannic acid* is a hygroscopic yellow powder of astringent taste, reducing iron with a greenish-black color; it dissolves readily in water and spirit, and precipitates mucus and albumen. *Phæoretin*, as well as *aporetin*, *erythroretin*, is a not very well-defined resinous substance, existing only in minute quantity. The composition of Rhubarb, as at present known, does not give much clew to its quality.

ACTION AND USE.—When chewed Rhubarb stimulates the saliva. In small doses, in the stomach, it seems to act as a digestive stimulant; in larger ones it appears to be a simple purgative, hastening along the contents of the bowels by increased peristalsis, carrying the liquid contents of the small intestine rapidly down, to soften and force along the more solid mass in the colon and rectum. Intestinal secretion is supposed to be less stimu-

lated by it than by salines or the cathartic resins. Its coloring matters are absorbed, and may tinge the milk and urine. Really our knowledge of the details of the action of this, and many other vegetable cathartics, is much more vague than is desirable. Their gross action is evident enough, and the comparative liability to produce nausea, vomiting, colic, collapse, etc., is pretty well understood; but how much is peristalsis, how much retarded absorption, how much increased secretion, how much biliary stimulation, is known of very few. Rhubarb is mild and pretty certain; it produces comparatively little pain, no depression in moderate doses, and its action is not prolonged. The tannin in it is credited with producing some constipation after its use, but the simple emptying of the bowels without irritation of the mucous membrane would be enough to explain this result. Rhubarb is given in almost all conditions where simply emptying the bowels is desired.

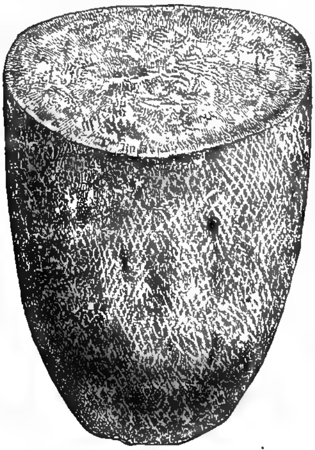

FIG. 3341.—Piece of Round Chinese Rhubarb, showing the white lozenge-shaped reticulation on its surface and the irregular medullary rays on the section. (Baillon.)

ADMINISTRATION.—Rhubarb is offered by the Pharmacopœia in a great variety of forms; it is also found in a good many of the popular proprietary laxative mixtures. It makes a fine, deep-yellow powder which is sometimes given, but not often, on account of its very nauseous taste. Two or three decigrams (gr. iij. ad v.), once or twice a day, would be a very mild tonic-laxative dose; a single dose of a gram (gr. xv.) is mildly, while one of two grams (gr. xxx.) would be severely, cathartic. Rhubarb in substance is frequently taken by chewing and swallowing a piece of the root as large as a pea or a bean, once a day or so, preferably after eating; the taste in this way being less nauseous than that of the powder. The tonic, almost carminative, action of Rhubarb upon digestion, has made it widely used in this way. The following are the preparations of the U. S. Pharmacopœia:

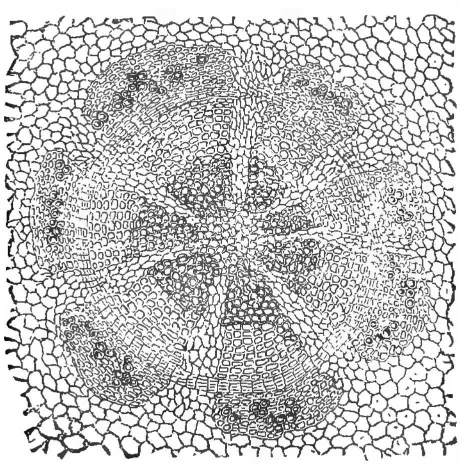

FIG. 3342.—One of the "Stars" of the Cambium Zone; magnified. (Baillon.)

Extract (*Extractum Rhei*), made by exhausting with alcohol and water, and evaporating; strength about $\frac{4}{1}$; useful for pills and mixing with other pill-masses.

Fluid Extract (*Extractum Rhei Fluidum*), strength, $\frac{1}{1}$, less used than the tinctures, is an ingredient of the following:

Mixture of Rhubarb and Soda (*Mistura Rhei et Sodæ*):

Bicarbonate of Soda	30 parts.
Fluid Extract of Rhubarb	30 "
Spirit of Peppermint	30 "
Water enough to make	1,000 "

It is an excellent laxative for indigestion, or diarrhœa with fermenting intestinal contents.

Pills (*Pilulæ Rhei*): Rhubarb, three parts; soap, one part; each pill contains three grains of Rhubarb.

Compound Pills of Rhubarb (*Pilulæ Rhei Compositæ*): Rhubarb, two grains; Purified Aloes, one and a half grain; Myrrh, one grain; Oil of Peppermint, one-tenth of a grain, in each pill.

Compound Powder of Rhubarb (*Pulvis Rhei Compositus*): Rhubarb, twenty-five parts; Magnesia, sixty-five parts; Ginger, ten parts. Corresponds to the mixture.

Tincture of Rhubarb (*Tinctura Rhei*), strength, $\frac{12}{100}$, with $\frac{2}{100}$ of Cardamom.

Aromatic Tincture (*Tinctura Rhei Aromatica*) contains:

Rhubarb	20 parts.
Cinnamon	4 "
Cloves	4 "
Nutmeg	2 "

Diluted Alcohol enough to make one hundred parts. The most desirable preparation as a general cathartic.

Sweet Tincture (*Tinctura Rhei Dulcis*):

Rhubarb	8 parts.
Glycyrrhiza	4 "
Anise	4 "
Cardamom	1 "

Diluted Alcohol enough to make one hundred parts. A desirable preparation for children, as the licorice masks somewhat the disagreeable taste.

Wine (*Vinum Rhei*), strengh $\frac{1}{10}$, with $\frac{1}{100}$ of calamus in sherry wine, a duplicate of the tincture.

Syrup (*Syrupus Rhei*):

Rhubarb	90 parts.
Cinnamon	18 "
Carbonate of Potassium	6 "
Sugar	600 "

Water enough to make one thousand parts. Like the sweet tincture, the sirup is a very popular cathartic for infants and children.

ALLIED PLANTS.—The genus contains about twenty species, most of whose roots have qualities similar to the above. Several of these, *R. Rhaponticum*, and others, are cultivated in Austria and elsewhere in Europe for this

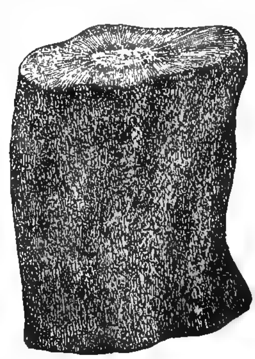

FIG. 3343.—European Rhubarb. (Flückiger.)

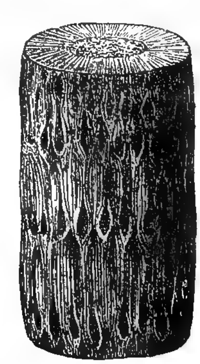

FIG. 3344.—European Rhubarb. (Flückiger.)

purpose, and the European product is trimmed and prepared so as to closely imitate the Chinese. It can generally be told by its duller color, more spongy texture, absence of gritty crystals when chewed, and the more regular arrangement of its medullary rays; the stellate

spots are absent. The foliage of Rhubarbs is bitter and sour; by cultivation the above and several other species have developed very large and pleasantly acid petioles, which, especially if partially blanched or shaded, make a delicious vegetable for tarts and stews. Malic and oxalic acids and their salts, and nitrate of potassium, are among their constituents.

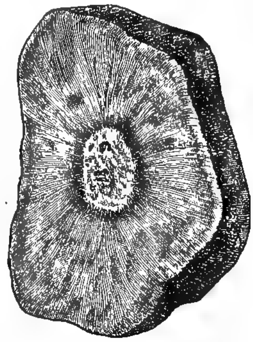

Fig. 3345.—European Rhubarb; surface of a transverse section. (Flückiger.)

The order contains besides: Bistort, *Polygonum Bistorta* Tourn; Buckwheat, *Fagopyrum esculentum* Mönch; Docks and Sorrels, *Rumex sp. var.* These latter (docks) resemble Rhubarb somewhat in the composition of their roots, but as their tannic matters are in excess of their laxative ones, they are not cathartic.

Allied Drugs.—The different species of *Rhamnus* (Buckthorn, Cascara Sagrada, Frangula, etc.) appear, in their action on the bowels, and, in some respects, in composition, to be more like Rhubarb than most cathartics. Senna, Wahoo, Blue Flag, and Podophyllin in small doses may also be mentioned, as well as perhaps Castor-oil. Aloes acts more upon the large intestine, the drastics and salines are more depressing, hydragogue, and violent. Sulphur and Magnesia are less active, but not dissimilar in kind to Rhubarb. None of them has the later astringent effect of the one under consideration.

The following list of substances used to increase the movements of the bowels, partly from Brunton, appears to be very well arranged:

Laxatives: Honey, Molasses (and food made with it), Manna, Cassia Fistula, Tamarinds, Figs, Prunes, Stewed Apples, Sulphur, Magnesia.

Simple Purgatives: Aloes (?), Rhubarb, Senna, Frangula U. S., Cascara Sagrada, Castor-oil, etc.; also Calomel (single dose).

Drastics: Elaterin, Colocynth, Jalap, Scammony, Gamboge, Podophyllin, Croton-oil.

Salines: Sulphate of Soda, Sulphate of Magnesia, Phosphate of Soda, Tartrate of Potassium, Bitartrate of Potassium (very mild), Citrate of Magnesium.

Cholagogues: Aloes, Rhubarb, Mercury (various preparations), Enonymin, Iridin, Podophyllin.

W. P. Bolles.

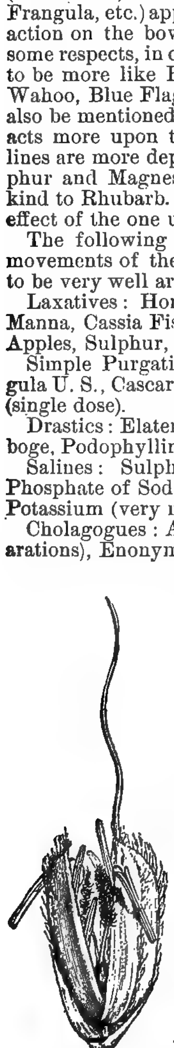

Fig. 3346.—Flower of Rice. (Baillon.)

RICE (*Riz*, Codex Med.). The grain of *Oriza sativa* Linn., Order, *Gramineæ*. A water- or swamp-grass originally from India, cultivated there for ages, early introduced into Southern Europe and the warmer parts of America, and forming the principal food-product of many tropical races of men. It has been divided into numerous garden varieties differing in the length of its glumes, color, size, and shape of its grains, etc.

For use, the grains are deprived of their husks and pericarps by beating, rubbing, or passing between rollers, by which means the embryo also is shelled, or rubbed out. The prepared grain, consisting entirely of the perisperm, needs no description. It has a smaller amount of mineral and albuminous constituents than other cereals, and a larger amount of *starch* (eighty-five to ninety per cent.). Rice starch is also a commercial product; it consists of exceedingly minute polyhedral granules. (See Starch.)

Rice has no medicinal properties, it is simply an almost pure farinaceous food, and is neutral and unirritating to the bowels; on this latter account it is often given in dysentery and diarrhœa. Rice-water, made like barley-water, by boiling whole rice in a large proportion of water and pouring off the clear liquid, contains a little soluble starch, and is employed as a demulcent drink.

Allied Plants, etc., see Starch. *W. P. Bolles.*

RICHFIELD SPRINGS. *Location and Post-office*, Richfield Springs, Otsego County, N. Y.

Access.—By the New York Central & Hudson River, the New York, West Shore & Buffalo, and the Delaware & Lackawanna Railroads.

Analysis (Professor C. F. Chandler).—One gallon contains:

	Grains.
Hydrosulphate of sodium	1.7189
Hydrosulphate of calcium	0.0908
Sulphate of potassa	1.6656
Sulphate of lime	112.3379
Sulphate of strontia	0.0105
Sulphate of barium	trace
Sulphate of magnesia	5.1498
Hydrosulphite of soda	0.3801
Bicarbonate of magnesia	31.7403
Bicarbonate of iron	trace
Phosphate of lime	0.0067
Chloride of sodium	0.5249
Chloride of lithium	0.0165
Alumina	trace
Silica	0.6415
Total	154.2835
Gas.	Cubic inches.
Sulphuretted hydrogen	14.206

The above analysis is of the water of "The Great White Sulphur Spring."

Therapeutic Properties.—These well-known sulphur waters are among the best of their class. The picturesque situation and classical associations add materially to the popularity of the resort. The diseases for which these waters are famous are chronic catarrhs, rheumatism, and skin affections.

Richfield Springs is situated about sixty miles west from Albany, on Canaderaga Lake, at an altitude of seventeen hundred feet. The surrounding country is devoted to farming, and affords many beautiful drives, especially about Otsego Lake, five miles distant, famous as the scene of some of Cooper's "Leather-stocking Tales." The hotel accommodations are first-class and ample. Of late years Richfield has become a favorite and popular summer resort. *George B. Fowler.*

RICKETS. Syn.: Rachitis; Fr., *Nouure, Rachitisme;* Ger., *Englische Krankheit.* A disease of childhood, arising from perverted nutrition, affecting nearly every tissue of the body, but chiefly and most constantly characterized by a softening of the bones, with resulting deformities. It occurs most frequently in children under three years of age, the greater number of cases apparently originating during the second year of life, at the period when weaning is usually accomplished; and though the bone symptoms may make their appearance at a later period than the end of the third year, careful inquiry will generally establish the fact of the occurrence of some of the manifestations of the disease in earlier life.

The *etiology* of rickets is obscure. It is usually supposed to be due to insufficient or improper food and impure air. Yet, though of undoubted importance, these are not the sole factors in the causation of this disease; for of the thousands of children living in the crowded tenements of our cities, constantly inhaling a vitiated atmosphere, and seldom receiving proper nourishment, but few, comparatively, are the subjects of rickets. On the other hand, the children of well-to-do parents, living under vastly better hygienic conditions, are by no means exempt.

Parrot advanced the theory that rachitis is a development of hereditary syphilis; but he stood almost alone in this view, and since his death the theory has had few supporters. Fournier, indeed, asserts that rachitis is so frequent among children the subjects of hereditary syphilis, that there must be some relation between the two

affections. He believes that syphilis may act indirectly as a cause by producing malnutrition. But this is very different from the theory of Parrot, who believed that hereditary syphilis was the sole cause of rickets; that rickets, indeed, *was* hereditary syphilis. In the "Report of the Collective Investigation Committee of the Norwegian Medical Association" (Christiania, 1887) it is stated that, out of two hundred and forty-two cases of rickets, it was possible to find some evidences of syphilis in the parents in only nine instances.

Oppenheimer assumes the disease to be a manifestation of malarial poisoning, basing his belief upon the periodicity that has been frequently observed in some of the symptoms. He states that rickets occurs chiefly in localities in which malaria is most prevalent; but this assertion is not borne out by observation, for the disease is of greatest frequency in cities, where malaria is weakest, and is very rare in tropical regions, where the most pernicious forms of malaria prevail.

It has been asserted that the children of young parents are more often rachitic than those of older parents, but the writer has been unable to verify this assertion by a study of the statistics at his command.

The influence of heredity has been denied. It is an undeniable fact that the mothers of rachitic children often themselves show evident traces of the disease, but this may possibly be ascribed to the fact that they were brought up under similar conditions. That there is, however, at least a racial predisposition to rachitis, is a fact of daily observation. In this country the disease is seen for the most part in children of parents born in European countries, with the exception possibly of the Irish, among whom it would seem to be for some reason less common than among those of the Anglo-Saxon and Latin races. The children of white native Americans are comparatively seldom attacked, but negroes are almost without exception rachitic. This predisposition to rickets in the colored race would seem to be an acquired one, for it is said that native Africans seldom, if ever, show any evidences of the disease.

The first symptoms are often developed during convalescence from whooping-cough or some other of the debilitating diseases of childhood. In the present state of our knowledge the most that can be said is that rickets is a disease occurring in children predisposed by hereditary or racial influences, in whom the assimilative functions have become impaired by poor food, bad air, absence of sunlight, or the influence of debilitating disease.

Pathology.—Of the pathology of rickets even less is known definitely than of its etiology. Numerous theories have been advanced, most of which are, however, based solely upon the changes observed in the bony structures, leaving out of consideration the pathological processes occurring in other tissues.

The urine in this disease contains an excess of phosphates, while the bones are markedly deficient in earthy constituents; and upon this fact is based the theory of an increased formation of acid in the system, whereby the earthy materials are dissolved out of the osseous structures. The nature of this acid, however, has never been determined, and its existence even remains a matter of conjecture only.

The changes occurring in the bones are much too complicated and varied to admit of a purely chemical explanation. The new bone formed beneath the periosteum is soft and deficient in earthy matter, and the animal matter seems also to be abnormal, as it has been found by some observers not to yield gelatine on boiling. The epiphyses are enlarged, and ossification at these points proceeds slowly and with great irregularity. The border of ossification does not present a clearly defined, straight line, as in normal bone, but is serrated, the new bone shooting far up into the cartilage in some places, while at other points streaks of unossified cartilage are observed extending for some distance along the shaft of the bone. The medullary cavity is advanced beyond the border of ossification, and is filled with a reddish pulpy matter. The lamellæ of bone are loosely imposed one upon the other, so that sometimes, in fresh specimens, they may be peeled off like the layers of an onion. Spontaneous incomplete fractures not infrequently occur, giving rise to much of the deformity usually attributed to a simple bending of the bone. Separation at the epiphysis (diastasis) may also take place, and when occurring at the hip may simulate congenital dislocation.

Ossification in the flat bones proceeds in the same irregular manner. In the cranium the fontanelles remain open for a long time, the sutures are not firmly united, and are apparently depressed, owing to an elevation along the borders of the bones similar to the enlarged epiphyses of the long bones. The earthy matter is not deposited regularly, but here and there soft spots may be felt in which the osseous formation is wanting. This deficiency is most common in the occipital bone, and constitutes the condition known as craniotabes.

The liver, spleen, and lymphatic glands are frequently enlarged and harder than normal. The brain is often hypertrophied, the change involving chiefly the white substance. The muscles are flabby, poorly developed, and on section seem to be paler than normal. The ligaments are nearly always relaxed.

Symptoms.—The earliest stage of rickets is characterized by no pathognomonic signs, and may readily escape recognition. The only symptoms are those of imperfect nutrition. The appetite is good, but the child does not seem to thrive. It is a little peevish and out of sorts, and the usual means resorted to by the mother or nurse to restore good nature are unavailing. It is most contented when alone, and resents any playful overtures, especially objecting to being tossed in the air or trotted upon the knee, sports which perhaps occasioned delight at an earlier period of its existence. Growth is retarded, the rounded cheeks and plump limbs lose their chubby outlines, and the child looks puny and wizened. Occasional attacks of diarrhœa may alternate with obstinate constipation.

Now the disease is established and its true character becomes revealed. The desire to be let alone becomes more positive, and is due to a hyperæsthesia of the skin, so that even a light touch may cause actual pain. The little patient will lie quietly for hours in its crib if undisturbed, but cries and betrays apprehension upon the mere approach of anyone who, it fears, is about to lift it. The weight of the bedclothes even seems to cause pain or discomfort, and, perhaps in consequence of this, the child is found uncovered as often as it is visited by the mother or nurse. There is profuse sweating, especially about the head, to such a degree oftentimes that the pillow is soaked by the perspiration. The action of the bowels is irregular, and attacks of diarrhœa with very offensive stools frequently occur.

The muscles become soft and flabby. Some writers speak of a rachitic paralysis, but this is incorrect; the muscles are weak and often atrophied, but the atrophy is rather that of disuse, and no real paralysis exists. The ligaments are relaxed, and the joints are in consequence abnormally movable. The child makes no attempts to walk or stand, but cries if placed upon its feet. Sometimes it is even unable to sit up; the back is bowed, and the head lolls from side to side, the patient having no power to steady it.

The teeth appear late and at irregular intervals; they are poorly formed, and early become carious.

There is but little, if any, elevation of temperature. The appetite usually is good, sometimes excessive, and thirst is a fairly constant symptom.

The picture here presented is that of the early stage of typical severe rachitis, prior to, and during the commencement of, the stage of softening of the osseous tissues. The symptoms vary greatly in severity, sometimes being so slight as to escape remark by the mother; but careful questioning will usually elicit the admission that the child was noticed to perspire freely, and that it had a habit of constantly throwing off the bedclothes. The most painstaking investigation will not seldom fail to develop any fuller history than this.

The second stage is that of softening of the bones, through which many of the characteristic deformities of

rickets are produced. All the bones of the body are subject to this change, though, in mild cases, the deformity is chiefly confined to the lower extremities, which become bent under the weight of the body. It is probable, also, that the muscles have some part in the production of the deformity in the long bones. But the more common occurrence of distortion in the lower extremities is seemingly due to the fact that these members have to bear the weight of the body. The upper extremities are less often bent, and when they are curved to any extent it is generally because the child has been allowed to crawl, thus throwing some of the weight on the arms. During this period the symptoms of the first stage usually continue, though with decreasing severity; or, in the milder cases, a marked amelioration may take place; the muscles regain their strength, the ligaments grow less yielding, the outlines of the limbs become rounded, and the child gains rapidly in weight. But this improvement in the general health has its disadvantage in causing increased deformity of the lower extremities, by forcing them to sustain a greater weight while the bones are still more or less yielding.

The head, in a typical case of rachitis, is elongated, and flattened upon the top and at the sides, the occiput is projecting, and the frontal bosses are prominent, thus giving to the head, when viewed from above, a rectangular appearance (*tête carrée*, caput quadratum). The features are small, and the cranium in consequence appears to be greatly enlarged, when it really may be smaller than normal. Dr. Henry N. Read (*New York Medical Journal,* August 29, 1885) states that the ratio of the greatest antero-posterior diameter to the base-line of the cranium is altered. Normally this should be, as pointed out by Dr. Samuel Gee, as 6 : 5. But in rickets Dr. Read has found that the antero-posterior diameter of the cranium is always lengthened in proportion to the base-line; in a case reported of not very marked rachitis this ratio was as 7+ : 5. There is sometimes an actual increase in size, due to hydrocephalus. The fontanelles are open, the sutures loosely knit, and lying in a groove caused by the prominent edges of the bones on either side. The soft spots in the occipital bone, due to imperfect ossification, may sometimes be felt. This condition (craniotabes) is said to be one of the earliest and most constant anatomical features of rachitis. The writer has not, however, found it with anything approaching the constancy asserted of it by most authors.

The ligaments and muscles of the spine are weak, the bodies and intervertebral cartilages are soft, and the consequent deformity is a posterior curve (kyphosis) in the dorsal region, with at times compensatory lordosis of the cervical and lumbar portions; usually, however, the kyphosis is complete and involves the entire length of the spinal column. Lateral curvature, or scoliosis, due to rickets, is a much less common deformity than kyphosis, though it is by no means rare.

The scapula usually suffers but little change; sometimes it is thickened, but more often is smaller than normal. The clavicle is thickened, its articular ends are enlarged, and it presents an exaggeration of its normal curves. Deformity of the arm and forearm, when at all pronounced, is found generally in children who cannot walk, but crawl upon their hands and knees. The curve of the humerus is outward, with its greatest convexity at the point of insertion of the deltoid muscle. The convexity of the curve of the forearm shows itself on the dorsal aspect. A very constant sign of rachitis, even in slightly marked cases, is the enlargement of the epiphyses at the wrist, the swelling being the more readily appreciated here because of its superficial location.

The softening of the ribs, when marked, is a constant source of danger, owing to the impediment thereby offered to free respiration. The heart is also very constantly hypertrophied in marked cases, in which the softening of the chest-walls is pronounced. The thorax is bulging at the sides, but the ribs recede before uniting with their cartilages, forming a groove running from above downward and inward on each side of the anterior wall of the chest. Each rib is enlarged at its junction with the cartilage, forming a row of knobs just anterior to the depressed line, and which has been called the rachitic rosary. The sternum projects forward in fancied resemblance to the keel of a ship, or the breast-bone of a fowl (pectus carinatum, chicken-breast). The lower ribs are flaring, being pushed out by the enlarged liver and spleen. The abdomen is swollen from the same cause, and also from flatulent distention of the bowels, which occasions much suffering to the little patient.

The deformity of the pelvis in the female may prove a serious obstacle to parturition in later life. The sacrum projects forward, and the acetabula are pushed in by the weight of the trunk; a horizontal section of the true pelvis thus presents the appearance of a trefoil.

The neck of the femur forms a more nearly right angle with the shaft than is normal; the latter is bowed outward and forward. The deformity sometimes consists of a sharp curve, with the concavity looking outward, at the lower end of the femur, producing one form of knock-knee; the tibia also sometimes presents a bend at its upper part, similar to that of the lower end of the femur, which contributes to produce the same deformity. Bow-legs is caused by an outward curve of the tibia, or of the tibia and femur, associated usually with a relaxed condition of the lateral and crucial ligaments of the knee. The tibia not infrequently presents an anterior curve at its lower third. The fibula usually follows the curve of the tibia, though in rare cases it may remain straight, in which case the external malleolus will project too low down and cause pain and difficulty in walking. The malleoli are enlarged and prominent. Flat foot (talipes valgus) frequently results from stretching of the plantar fascia, with consequent breaking down of the arch of the foot, and also from softening of the bones of the tarsus.

The chief cause of the deformities in rickets is the weight of the body acting upon the long bones of the extremities and causing them to bend or break; not infrequently the curves are due to a green-stick fracture rather than to a simple bowing. Muscular action is, however, a frequent, and sometimes the sole, factor in the production of deformity. The misshapen thorax is a result of atmospheric pressure and muscular contraction combined.

The last stage of rickets is the stage of cure. The constitutional disturbances, in cases in which they have continued through the second stage, now subside, and the child seems again to enjoy the perfect performance of all the animal functions. The bones become firm from a deposition of the earthy constituents, but there is not a simple restoration of the osseous structures to the normal; for, with the irregularity peculiar to rickets, in which the balance-wheel of the animal machine seems to be wanting, there is an excess of action; the process of ossification, so long delayed, now runs wild, and the soft animal matter becomes converted into ivory rather than bone. Any deformities which have been overtaken by this process, called eburnation, while still uncorrected, become fixed and incapable of cure by other than operative measures.

Sometimes a spontaneous straightening of the bowed limbs occurs during this stage. This occurrence is difficult of explanation, but it is possibly due to an increased growth on the concave side of the bone.

A child who has been profoundly affected with rickets never attains the full stature which he would have reached had he remained free from the disease. In a given family, the children who have suffered from rickets, even though they be free from deformity, are always shorter than their unaffected brothers and sisters.

The *prognosis* of rachitis, apart from its complications, is favorable as regards life; very few children die from rickets alone, but many succumb to bronchitis and laryngismus stridulus, appearing as complications of the disease. A simple bronchitis, which would pass almost unnoticed in a healthy child, becomes a most serious disease in one affected with rickets, in whom the ribs are soft and yielding. The elasticity of the thoracic walls is impaired, the lungs can neither receive nor expel a normal amount of air, and when a further impediment is added to respi-

ration by the presence of inflammatory secretions, the condition of the child becomes precarious indeed.

Another complication, through which the life of the child is jeopardized, is laryngismus stridulus. This affection is stated by some writers to occur only as a consequence of rickets, the origin of each attack being attributed to cerebral pressure from the weight of the softened cranium resting upon the brain. It certainly occurs most frequently, if not solely, in rachitic children.

The prognosis, as regards deformity, if mechanical treatment be neglected, is unfavorable. The curved bones, it is true, do at times straighten themselves as the disease subsides, but such a favorable result is doubtful, and can seldom be predicated in any individual case. But little can be done by way of prevention of the pelvic deformity, the consequences of which in after-life, in females, are often most serious. A spontaneous rectification of this deformity seldom, if ever, occurs. Fortunately it is of rare occurrence, except in the most severe forms of the disease.

The *treatment* of rachitis is twofold, viz., the treatment of the disease, and the prevention or correction of deformity. All measures which tend to improve nutrition are beneficial. Light and airy sleeping apartments, easily digestible and not too watery food, pure mountain or sea air, plenty of sunlight, perfect cleanliness, all are of the utmost importance. A change should always be sought; if the child live near the sea, mountain air is more likely to be of benefit, and conversely, those from inland towns should be taken to the sea-shore. Salt-water baths, in moderation, sometimes prove in the highest degree beneficial. Unfortunately, the children of the poor, living in the crowded quarters of large cities, are seldom able to avail themselves of such treatment. Yet much may be done, even here, by a more careful observance of some of the simplest rules of hygiene, to give instruction in which is the first duty of the medical attendant. The child may be taken every day, or every other day, to the parks or outskirts of the city; or, if the town is by a river, to the water's edge or upon a ferry-boat. If the parents live on the first floor of a tenement-house, they should seek rooms on the upper floors, where the air is presumably less impure. Great care should be taken in guarding against the sudden changes of our climate, since even a slight bronchitis is liable to prove fatal. As these children always lie uncovered, in spite of the most watchful care, they should sleep in flannel garments which cannot be thrown off. Cod-liver oil and the compound syrup of the hypophosphites are useful when they are not rejected by the stomach; they may be administered in combination, or the oil may be given in winter, and the hypophosphites in summer. Eucalyptus globulus, in doses of ten to forty minims of the tincture, three or four times a day, is said to be often very beneficial.

Much has been written of late years for and against the use of phosphorus, as recommended by Kassowitz, in the treatment of rachitis. Many regard this drug as a real specific in rickets, while others, after a long experience, condemn it as useless, if not harmful. The writer's experience with it has not been sufficiently extensive to warrant him in expressing a positive opinion. But in some dozen cases in which he has tried it, it has seemed to be of service. No bad effects were observed. The dose is $\frac{1}{500}$ to $\frac{1}{200}$ grain twice or three times a day. The phosphorus should not be given dissolved in cod-liver oil, as recommended by some, for such a mixture is not permanent, and soon becomes inert. The ethereal solution and the solution in bisulphide of carbon are probably the best forms in which to administer it. The latter may be prepared after Hasterlik's formula as follows:

℞.	Phosphori	0.01 (gr. $\frac{1}{6}$).
	Carbonei bisulphidi	0.25 (gr. iv.).
	Aquæ destillatæ	100.00 (℥ iij.).
M.		

The dose of this is half a teaspoonful, which may be given in syrup, or, preferably, with an equal amount of cod-liver oil. The solution should be kept in a well-stoppered bottle away from the light.

Treatment of the deformities should be instituted early, before the bones become hard, and should be persevered in without intermission. The mechanical treatment of rachitis is no less important than the hygienic and medicinal, and in no case should it ever be neglected under the idea that the deformities will correct themselves. No child who has received intelligent instrumental treatment need grow up with crooked legs or a crooked spine as a result of rickets, and every adult who suffers from such misfortune is a living witness of parental or medical neglect. For the management of the special deformities, see under their respective headings.

Thomas L. Stedman.

RIO DE JANEIRO. The accompaning chart, representing the climate of the city of Rio de Janeiro, Brazil, is likely to interest some of the readers of the REFERENCE HANDBOOK, as giving them a fairly typical showing of a truly tropical climate (although, to be sure, not an extreme example of this class), and also as conveying more accurate information than is generally possessed respecting the climate of the largest commercial city of the South American continent. As a health-resort proper, Rio de Janeiro is not for a moment to be considered; but as a temporary halting-place for invalids undertaking a long sea voyage it is worthy of consideration. A knowledge of its climate will also be of service to such business men as are, by the necessities of their calling, compelled or prompted to make this city a place of more or less permanent residence.

Foreigners, whenever possible, would do well, however, to make some one of the higher-lying towns of Brazil, situated at no great distance from Rio, their place of residence, at least during the warmer months, in order to escape the continuous heat and great atmospheric humidity which combine to make the climate of the city itself so debilitating. The German colonies of Petropolis and Novo Friborgo may be specified as good places of resort at this season. Petropolis is but two and a half hours' distant from Rio, and Mr. C. C. Andrews, in his work on Brazil, tells us that "a few business men make the round trip daily." Novo Friborgo lies one hundred and twenty miles to the northeast of Rio. For an interesting account of the climatic conditions prevailing at the last mentioned of these two places, see the London *Lancet* of July 19, 1884. The high ground immediately back of the city will also be found more comfortable and more agreeable as a place of residence than the low-lying and thickly built business portion of the town.

Yellow fever, which was formerly a great scourge at Rio, has become of late years far less prevalent. Smallpox appears to be endemic, as in most, if not all, of the larger cities of South America, and as in many of the large cities of Europe.

The climatic chart of Rio, here published, was very kindly obtained for the writer by his friend, Mr. Charles L. Jacobson, and was prepared by Mr. T. O. Gunton, of Chester, England. The following passage is extracted from Mr. Gunton's letter to Mr. Jacobson enclosing the chart, and dated Lisbon, May 8, 1885: "I have been unable to record the velocity of the wind, as I have no instrument for the purpose. However, the Rio climate may be thus very briefly described: In normal weather there blows a mere light air from the north, which is known as the land-breeze; then at 1 P.M., or thereabout, springs up the sea-breeze; a fresh breeze from the south and southeast (part of the trade-winds from southeast), lasting until about four or five o'clock, when it dies down, and the nights are usually calm and quiet. Only at periods of change of moon is this weather upset by an occasional sou'wester, when heavy rains are preceded by violent gusts of wind which develop into dust-storms, and then comes rain, heavy weather out at sea, which lasts two or three days; then the weather takes up again until next time.

"The figures are my own, except the rainfall, which was given me in millimetres, and I converted the figures into inches on the .03937 ratio."

In conclusion, the reader's attention is called to the fact

Climate of Rio de Janeiro.—Latitude 25° 54′ 23″ *S.; Longitude* 43° 8′ 34″ *W.—Period of Observations, January* 1, 1884, *to December* 31, 1884.—*Elevation of Place of Observation above the Sea-level,* 327 *feet.*

that the term "fair," as employed in column L, is not to be interpreted in the technical sense adopted by the United States Signal Service, and explained in the general article on climate (vol. ii., page 191), but is rather to be understood in the equally technical sense in which this term is used by English writers, viz., as applying to days on which no actual fall of rain occurs. Moreover, it is to be noticed that the duration of the period of observations upon which are based the data of this Rio chart was but a single year; the bearing of this fact, especially upon the interpretation of columns B, C, and D, is to be borne in mind. All of Mr. Gunton's figures for temperature were given in Centigrade, and have been by me converted into Fahrenheit. *Huntington Richards.*

RIPPOLDSAU is a spa in Baden, in which are four medicinal springs, three of which are employed for internal medication, and one for bathing. The names of the springs are the Badequelle, Wenzelsquelle, Leopoldsquelle, and Josefsquelle. The composition of the last named, according to the analysis of Bunsen, is as follows. One litre contains:

	Grammes.
Calcium bicarbonate	1.6847
Magnesium bicarbonate	0 0707
Ferrous bicarbonate	0.0514
Manganous bicarbonate	0.0043
Sodium sulphate	1.2130
Calcium sulphate	0.0557
Magnesium sulphate	0.2430
Potassium sulphate	0.0605
Magnesium chloride	0.0847
Alumina	0.0044
Silica	0 0572
Arsenic	trace
Total	3.5296

These waters are used chiefly in the treatment of congestive disorders of the abdominal viscera, and in anæmia. *T. L. S.*

RIVIERA. The article describing the Genoese Riviera will be found in the Appendix.

ROANOKE RED SULPHUR SPRINGS. *Location,* Roanoke County, Va. *Post-office,* Roanoke Red Sulphur Springs, via Salem, Roanoke County, Va.

Access.—By the Norfolk & Western Railroad to Salem, thence by stage to the Springs, nine miles.

Analysis (Professor M. B. Harden).—One gallon of 231 cubic inches contains:

	Grains.
Calcium carbonate	6.53650
Magnesium carbonate	5.82876
Lithium carbonate	0.01549
Manganese carbonate	0.01624
Iron carbonate	0.05852
Copper carbonate	trace
Sodium chloride	0.24401
Ammonium chloride	0.01801

Ammonium nitrate	0.05476
Alumina	0.00648
Silica	0.83851
Organic matter	0.76005
Arsenic	trace
	21.70197
Carbonic anhydride combined with monocarbonates to form bicarbonates	5.96680
Total	27.66877
Cubic inches of gas per gallon:	
Carbonic anhydride	12.40
Sulphuretted hydrogen	2.44

THERAPEUTIC PROPERTIES.—These are excellent alkaline, chalybeate, sulphur waters, of a mild and agreeable type.

The springs are situated in the southeastern part of Virginia, at an altitude of over two thousand feet above sea-level. The country is mountainous, with forests of pine, and there are many natural objects of interest within driving distance. The hotel and cottages furnish ample accommodations for two hundred and fifty guests. *G. B. F.*

ROCHEFORT is an important town in France, situated on the Charente River, near its mouth. There is an artesian well here, the water of which, issuing at a temperature of 105° F., is employed, both internally and externally, for therapeutic purposes. The following is its composition, according to an analysis of M. Roux. One litre contains :

	Grammes.
Sodium sulphate	2.590
Calcium sulphate	1.323
Magnesium sulphate	0.504
Sodium chloride	0.754
Magnesium chloride	0.023
Calcium chloride	0.034
Calcium carbonate	0.313
Magnesium carbonate	0.033
Ferrous carbonate	0.035
Alumina	0.005
Silica	0.017
Iodine, bromine, organic matter, etc	0.083
Total	5.714

There are also traces of manganese and arsenic.

This water is employed in the treatment of engorged conditions of the abdominal organs, in anæmia, and in debility during convalescence from acute diseases. Externally it is used to promote the healing of indolent ulcers, to stimulate granulations, and hasten cicatrization. *T. L. S.*

Climate of Rochester, N. Y.—Latitude 43° 8′, *Longitude* 77° 42′.—*Period of Observations, November* 1, 1870, *to December* 31, 1883.—*Elevation of Place of Observation above the Sea-level,* 500 *feet.*

ROCHESTER. The accompanying chart, representing the climate of the city of Rochester, N. Y., and obtained from the Chief Signal Office, at Washington, is here introduced for convenience of reference. A detailed explanation of this and of other similar charts is given in the general article on Climate (vol. ii., pages 189 to 191), where also the reader will find suggestions as to the best method of using these charts.

Rochester lies in the so-called "Lake Region" of the United States, the city itself standing but seven miles distant from the southern shore of Lake Ontario. A reference has already been made to the winter cloudiness characterizing the climate of this district (see under Portland, Me., on page 782 of vol. v.). A comparison of columns K, L, M, N, and O in this Rochester chart, with the like columns in the chart for New York City, will demonstrate the decidedly greater cloudiness and relative humidity during the winter season at Rochester. The rainfall, which at New York is seen to be least in winter, is, at Rochester, least in autumn ; but throughout the year the quantity of the rainfall is more evenly distributed at the latter than at the former place, winter not being that *comparatively* rainless season at Rochester which it is at New York, although the winter rainfall of the two places is very nearly the same, and is, in fact, slightly greater at New York than at Rochester.

On the other hand, during the six months, April to September, inclusive, the relative humidity of the atmosphere is markedly lower at Rochester than at New York, and the cloudiness is nearly the same at the two places ; during the mid-summer months actually less at the former than at the latter. Thus, during the winter season Rochester is decidedly damper and more cloudy than New York ; during the summer season, and especially

the mid-summer season, New York is markedly damper and a trifle more cloudy than Rochester.

H. R.

ROCKBRIDGE ALUM SPRINGS. *Location and Post-office,* Rockbridge Alum Springs, Rockbridge County, Va.

ACCESS.—By the Chesapeake & Ohio Railway to Goshen, eight miles from the Springs.

ANALYSIS.—One pint contains:

Carbonic acid	0.7	1.9	1.1

THERAPEUTIC PROPERTIES.—There are here nine alum springs and one pure chalybeate, and their remedial value is attested by the decided cures effected in many instances. The alum waters are tonic and astringent. Their taste is astringent, and their temperature averages about 50° F. They cure catarrhal diseases of the alimentary and genito-urinary tract, and are famed for their beneficial influence upon chronic skin diseases, glandular enlargements, chronic ulcers, and, in fact, all scrofulous degenerations.

An experienced physician resides at the Springs, and directs the use of the waters.

The situation of these Springs is in the northwestern part of Virginia, in a glen at the base of North Mountain on the south and Mill Mountain on the north, amid the beautiful scenery of this section. The lawn, of about fifty acres, is partially surrounded by several fine hotels and cottages, affording accommodations for seven hundred guests. *Geo. B. Fowler.*

ROCKBRIDGE BATHS. *Location and Post-office,* Rockbridge Baths, Rockbridge County, Va.

ACCESS.—By the Baltimore & Ohio (Harper's Ferry & Valley Branch) Railroad to Timber Ridge Station, thence by stage to the baths, four and one-half miles.

THERAPEUTIC PROPERTIES.—These waters are principally employed as baths. They contain iron, lime, soda, magnesia, potassa, and iodine.

The springs are beautifully situated on the banks of the North James River, on the old stage road, passing through the celebrated Goshen Pass, from Goshen to Lexington, about ten miles from either place, amid some of the most picturesque scenery in Virginia. There are hotel accommodations at the baths. *G. B. F.*

ROCK CASTLE SPRINGS. *Location and Post-office,* Rock Castle Springs, Pulaski County, Ky.

ACCESS.—By the Louisville & Nashville Railroad (Knoxville & Bardstown Branch) to London, thence by stage to the Springs, eighteen miles.

THERAPEUTIC PROPERTIES.—This is one of the waters which should prove beneficial in disorders of digestion and allied complaints, simply from its purity; as the writer holds that the imbibition of pure water (in excess in disease) is one of the greatest aids in treatment.

ANALYSIS (Dr. Peters).—Composition in 1,000 parts:

	Grains.
Carbonate of iron	.0045
Carbonate of lime	.0438
Carbonate of magnesia	.0148
(Held in solution by carbonic acid.)	
Sulphate of lime	.0029
Sulphate of magnesia	.0036
Sulphate of soda	.0531
Chloride of sodium	.0026
Silica	.0128
Total	0.1381

The water contains 0.930 part per thousand, by weight, of free carbonic acid.

Rock Castle Springs is situated in Southeastern Kentucky, on the Rock Castle River, amid the wild and picturesque scenery of the Cumberland Mountains. The invigorating mountain air, the delightful atmosphere during the summer, the thermometer rarely rising above 85° F., and then for a few hours only, the nights being so cool as to require blankets during the entire season, and the grand scenery, have made this a favorable resort. The hotel, surrounded with wide verandas and a beautifully shaded lawn, has accommodations for two hundred and fifty guests. It is situated in a gorge at the base of a mountain four hundred feet high, and looks out on the river, on the opposite side of which there is a corresponding mountain height. Hunting, fishing, boating, excursions to the numerous points of interest in the neighborhood, bowling, etc., furnish ample amusement for the guests of the hotel. *George B. Fowler.*

ROCK ENON SPRINGS. *Location and Post-office,* Rock Enon Springs, Frederick County, Va.

ACCESS.—By Baltimore & Ohio Railroad (Harper's Ferry & Valley Branch) to Winchester, thence by stage to the Springs, sixteen miles and a half.

ANALYSIS (Professors Gale and Mew. Chalybeate Spring).—One gallon contains:

	Grains.
Carbonate of lime	5.13
Carbonate of soda	1.21
Carbonate of protoxide of iron	14.25
Carbonate of protoxide of manganese	1.05
Sulphate of magnesia	12.89
Sulphate of lime	3.56
Chloride of magnesium	1.12
Alumina	0.80
Silica	0.42
Total	40.43

THERAPEUTIC PROPERTIES.—This is a quiet retreat, and the use of the alkaline calcic waters has been of great service to many worn and exhausted constitutions. Accurate thermometric records show that the temperature during the summer never rises above 78° F.

Besides the Chalybeate there are two other mineral springs: "The Walnut," the water alkaline and its action diuretic and aperient, and "The Old Capper," efficacious in rheumatism and diseases of the skin. These three, together with five limestone springs, are close by the hotel. In the neighborhood are four sulphur springs of excellent quality.

Rock Enon Springs are situated in the northeastern part of Virginia, about forty miles west of Baltimore, on the western slope of the Great North Mountain, amid grand and picturesque scenery. The hotel possesses all the conveniences for the health, comfort, and amusement of its guests. It is supplied on every floor with pure water from the "Great Cold Spring" on Pinnacle Mountain, and the sanitary arrangements are complete. There are delightful walks and drives through the surrounding mountains and valleys.

The facilities for bathing are excellent, including hot and cold mineral and pure water baths, and a swimming pool seventy-five by twenty-five feet.

George B. Fowler.

ROCKY MOUNTAIN SPRINGS. *Location,* Boulder County, Col.; *Post-office,* Jamestown, Boulder County, Col.

ACCESS.—By Union Pacific Railway (Colorado Divis-

ion) from Denver to Boulder, thence by stage twelve miles to Springs.

ANALYSIS (C. T. Jackson).—One pint contains:

	Grains.
Carbonate of soda	0.474
Carbonate of magnesia	0.049
Carbonate of lime	5.414
Carbonate of iron	0.362
Chloride of sodium	0.620
Sulphate of soda	13.075
Iodide and bromide of sodium	0.162
Silicate of soda	0.500
Total	20.656

THERAPEUTIC PROPERTIES.—Mild alkaline, cathartic, and tonic waters.

These springs are situated in Northern Colorado, two miles from Jamestown, at an altitude of six thousand five hundred feet above sea-level. There are hotels and bathing facilities at the Springs. *George B. Fowler.*

ROETHELN. DEFINITION AND HISTORY.—Rötheln is an exanthematous disease of mild character, attended with a slight elevation of temperature, propagated by contagion, and bearing a close resemblance to measles and scarlatina. It is widely known in this country under the above appellation, and also, in common parlance, by the term "German Measles." The latter name being English, is generally used. Thus in its nomenclature Rötheln resembles the other exanthemata, which have each a technical and a common name. The Germans, however, use the names Rötheln and rubeola as synonyms; and this tends to confusion, since we signify by rubeola the different disease, true measles or morbilli. Various other names have been given to the disease by different writers, prominent among them being epidemic roseola, rubeola scarlatinosa, rubeola morbillosa, rubeola notha, and rubella. The last-mentioned name has been suggested as most appropriate, since it is a diminutive of rubeola, and thus the two words express the analogy existing between the two diseases, just as do the terms variola and varicella. For the reason, however, that Rötheln is more widely recognized, the writer retains it in this article.

Rötheln is, as far as definite knowledge is concerned, a new disease. As late as 1886 the "Index Medicus" gives it no separate place, and the articles on the subject are grouped under the heading of measles; yet the number of communications, treating of this affection, which have been written during the past ten years or so, will aggregate more than one hundred. Before that time, however, the disease had been from time to time spoken of, as far back as a century and over; though until the time of the present generation the greater number of observers did not consider it a distinct disease, but believed it to be a modification of measles, generally, and in some instances of scarlatina. Mention was made of epidemics in 1845 and 1853, and in 1873–74 the disease was carefully described, though under the name of epidemic roseola. In Germany attention was given to the subject many years before any English or American writings appeared. Now almost all physicians grant its individuality, and the arguments supporting this view will be presented hereafter.

AGE OF PATIENTS.—Rötheln is generally classed as one of the diseases of childhood; and, since there are no clearly proved instances of its second appearance in the same individual, it follows that those affected are usually young in years; the general rule being that any one of the contagious exanthemata is experienced but once in the lifetime of an individual. Still, it is much less prominently an affection of infants and children under five years of age than are the other eruptive fevers. Adults are frequently attacked, but the majority of those who suffer from this disease contract it some time before the age of puberty. In other words, the time of life when susceptibility is greatest is between the ages of two and fifteen years. Young infants do not seem to contract it, and it is believed that sucklings are not susceptible. As, however, it is a disease of less frequent occurrence than measles or scarlatina, and as it seems to be less actively contagious than those diseases, many growing children escape it; and these facts constitute a possible explanation of the circumstance that adults are not infrequently attacked during the prevalence of an epidemic.

The season of the year does not seem to exert any influence on its prevalence. Epidemics occur indifferently in hot and cold weather.

ETIOLOGY.—Rötheln is propagated by contagion, and by this means alone. The materies morbi is believed to be portable, but the cases in which the source can be traced point toward the necessity of close contact for the transmission of the disease from the sick to the well. In a single epidemic the total number of cases among those unprotected by having previously experienced the disease is found to be small in comparison with the other contagious exanthemata. Especially is this noticeable with reference to measles, which will attack, simultaneously or successively, all the susceptible children in a household almost with certainty; while we generally meet with a single, or perhaps two, cases of Rötheln, and the greater number of those exposed, in greater or less degree, escape. J. Lewis Smith, in one epidemic, saw forty-eight cases in twenty-one families—an average of a little more than two to each family. In an institution, such as an orphan asylum, the number of cases would be comparatively larger, since the exposure would be of necessity greater at first. Isolation, therefore, can be expected to accomplish more in the direction of prevention than it does with measles or scarlatina.

Rötheln is encountered almost exclusively in epidemics, and sporadic cases are very rare. This is probably more decidedly the case with Rötheln than it is with scarlatina, and possibly also with measles.

Considerable difficulty is experienced in tracing cases of Rötheln to their sources—largely, no doubt, because affected persons are frequently unconfined, owing to the general mildness of the disease, and the absence of alarm concerning it. Undoubtedly, however, if its origin could always be traced, an exposure to contagion would be discovered. In other words, it is practically certain that the disease does not originate *de novo;* nor is it produced by general causes, such as improper hygienic surroundings in the matter of poor ventilation, overcrowding, or insufficient or improper dietary conditions. On the contrary, it is not found to be a disease of greater proportionate prevalence in tenement-house districts, where the conditions referred to are in prominent existence. A large proportion of the cases are encountered in the families of the better classes, and, most of all, in institutions, such as orphan asylums.

We may reasonably conclude that Rötheln is less actively contagious than measles or scarlatina, since so many of those exposed escape. Under the same conditions of exposure the number of cases arising of either of those two diseases would probably considerably exceed those of Rötheln.

The age at which susceptibility is greatest has been mentioned, being considerably more advanced than that which obtains with the other exanthemata; but as yet there is little definite knowledge as to the stage of the disease itself in which propagation by contagion is most likely to occur. We can only say that the probability is in favor of contagiousness during the whole course of the disease—from the time when prodromal symptoms, if present, appear, until the eruption has entirely disappeared.

CLINICAL HISTORY.—*Stage of Incubation.*—Much attention has been given to the duration of the stage of incubation—the time elapsing between a traceable exposure and the onset of the disease. This is frequently made difficult of accurate investigation for the reason before mentioned, that isolation is not observed because of the mild character of the affection, and sometimes even confinement within doors is not enforced. The general experience is that this stage occupies from fourteen to twenty-one days; though in some epidemics the duration has been considerably less. Shuttleworth had the opportunity of ascertaining, in an asylum, that twenty-one days elapsed after the first case before the second oc-

curred, isolation being enforced, and two days later two fresh cases developed. Goodhart says that the incubation, in 23 out of 25 cases, was from fourteen to twenty-two days. Edwards gives six days as the shortest, and twenty-one days as the longest. Cheadle ascertained it to be eight days in one instance, nine in another, and (approximately) twelve days in five more. Griffith's experience was that in 26 cases the eruption appeared between the fifth and twelfth days after the first case. Therefore, it must be granted that considerable variation exists in the length of this stage, although we may consider that a period of fourteen days represents the average. The incubative stage of measles is much more constant—standing at thirteen and fourteen days.

Stage of Invasion.—In very many instances the eruption is the first thing calling attention to the existence of sickness. Since many of the patients are old enough to describe any subjective symptoms which may be present, it follows that the stage of invasion is frequently attended with little or no disturbance of general health. With children too young to describe their own sensations, the attention of parents is often attracted by no manifestation whatever—such as restlessness, or crying, or digestive disturbance—until the eruption becomes visible. It is, however, probable that there is always present a slight rise of temperature, not sufficient to cause discomfort; and close questioning might elicit an admission of a feeling of malaise. But, as stated, the breaking out of the rash is what causes uneasiness, and leads patients or parents to consult a physician for the purpose of ascertaining the nature of the sickness.

There are, on the other hand, cases in which there is more or less decided disturbance of health prior to the appearance of the eruption. Epidemics undoubtedly vary greatly in severity, as do individual cases in a single epidemic; and from the average of descriptions it would appear that the disease is more severe, as well as of more frequent occurrence, in Europe than in the United States. These more severe cases present certain indications of sickness, before the rash appears, which, taken in connection with known exposure, point toward Rötheln as the oncoming disease; but, in themselves, they have little value as regards the differential diagnosis, especially, from scarlatina and measles. The symptoms, when present, have special reference to the mucous membranes of the air-passages, and to the digestive system. They are: mild inflammation of the throat and tonsils, shown by swelling and redness on examination, and by pain and slight cough; a slight degree of coryza; conjunctival irritation, lachrymation, and a little tendency to œdematous swelling of the eyelids. Nausea and anorexia have been frequently observed, and in rare instances vomiting. Frontal headache in a few instances is the source of much discomfort. The digestive disturbances appear to have been prominent in some, and absent in other, epidemics. With these symptoms, and, it is not improbable, in their absence, there is a rise of temperature to 99° or 100° F. in mild, and as high as 103° in severe, cases. In addition to these indications there is one symptom highly characteristic of the fully developed disease, as will hereafter be seen, which has been observed in the prodromal stage. This is enlargement of the post-cervical lymphatic glands—not those at the angle of the jaw, as obtains in scarlatina and diphtheria, but those in the back of the neck. This enlargement should always be looked for, since it is the only feature of diagnostic value in the stage of invasion. Jaccoud found it, in five out of thirty-two cases, four or five days before the efflorescence. Associated with this, stiffness of the neck with pain on movement of the head, in slight degree, should be sought for.

Any throat inflammation present might easily be accounted for in expecting scarlatina to develop; and coryza, cough, and conjunctival irritation belong to the clinical history of measles. Rise of temperature also, of course, accompanies the onset of both these diseases; and consequently, excepting only the glandular enlargement, as far as these general symptoms are concerned, it is only in their lesser degree of severity that they are characteristic of Rötheln rather than of the other two affections.

These indications, when present, precede the eruption by a period, in the great majority of cases, of less than twenty-four hours; although in some instances malaise is present for three or four days before this stage is ended. Cheadle, in describing a severe epidemic, observed that the prodromal symptoms persisted longer in severe than in mild cases. Edwards gives the average duration as three days.

It is therefore observable that the stage of invasion, when present, is subject to considerable variation—both as to length and severity—and is, in fine, a much more uncertain quantity than is that of scarlatina or measles.

Stage of Eruption.—The prominent feature of the disease is the eruption, often, as before stated, being the only phenomenon perceptible, and generally being by far the most prominent manifestation of a condition of sickness. Very great differences, in different epidemics and in individual cases, are to be found; and, considering the eruption alone, a diagnosis might well be difficult, if not impossible. As the symptoms other than the eruption, such as those found in the prodromal stage, present considerable variation, and as this fact holds with the eruption itself, we may conclude that the disease, as a whole, is far less *stable* than scarlatina and measles. These are more than variations of degree—they affect the essential characters of the symptoms and of the eruption.

Scarlatina, for instance, may be very mild or very severe as regards the throat inflammation and fever; and its eruption may be difficult of detection, or as marked as a pronounced rash of erysipelas; but these are differences of degree, and the sore throat and eruption are uniformly present, and are *sui generis.* The same rule holds with measles. The essentials of the disease—the catarrh of the respiratory tract, and the characteristic eruption—may, one or both, be very mild or very severe; but they must both be present in any case where the diagnosis is undoubted. Rötheln, on the other hand, may consist, from beginning to end, of the eruption only, or may present some of quite a variety of symptoms affecting the mucous membranes of the air-passages or of the digestive apparatus.

Regarding the eruption itself, its characteristic points are as follows: Its color is generally a pale rose, less distinctly rose-hued than that of measles. It is very frequently brownish, brownish-red, and sometimes quite distinctly brown, with no tinge of rose or pink to be detected, and giving the general effect of duskiness.

As to location, no part of the surface is entirely exempt. The palms of the hands, the soles of the feet, and the scalp have been observed to present it; although usually it is not to be found in those regions. As a general rule, the face, trunk, arms, and legs break out successively before the final disappearance of the rash; although cases are often described in which the affected area is much less extensive.

Either the face or the upper part of the body may be first affected, and the spread of the eruption is rapid—one day or less sufficing for its appearance on the remoter parts after its initial appearance. The maximum of intensity is very quickly attained. Beginning on the face, for example, in very faintly marked spots, after a period of a few hours, and certainly within one day, it will be at its height, and the spots will be plainly visible. Then a fading process sets in, gradually progressing, accompanied with, or followed by, some desquamation, and continuing for about two days; so that, in any selected locality, from the first appearance to the final disappearance, an average period of three days is occupied. This, however, is not a definitely fixed time; sometimes it embraces but two days, and at other times it is protracted to six or seven.

The duration of the eruption as a whole, without reference to any special part of the surface, is consequently a little longer than that of its presence in a given locality—by the time occupied in the spreading from the region first to that last attacked. As this generally requires one

day, or somewhat less, the eruptive stage of the disease can be expected to continue about three days on the average, though subject to the variation spoken of, having as extremes two and seven days. It will be observed, from the rapidity of development in a selected locality as compared with the rapidity of the spreading to other regions, that different parts will present the eruption in greatly varying conditions; and that at no given time will it be at its maximum uniformly over the entire surface of the body. In other words, it may even reach its height in one part before appearing in another. This is a point of value in diagnosis, and of contrast to scarlatina and measles, in both of which there is generally a stationary period as regards the spread and intensity of the eruption after the maximum has been attained.

The eruption is papular. If the hand is passed gently over it, a sense of roughness, at least, is perceptible, showing a certain degree of elevation above the surrounding skin. From this very slight condition of elevation differences are to be found up to a state in which the elevation is distinctly and at once visible—as much so as in a fully developed rash of measles. But, in some degree, elevation of the spots is always present, and therefore it is a mistake to describe the eruption as macular.

The size of the papules is one of the points in which there is considerable variation. In general they are smaller than the papules of measles, varying from the diameter of a pin's head to that of a pea. In a certain proportion of cases the spots are so small as to constitute mere punctation, and the skin presents the appearance of being covered with innumerable fine dots. They are of irregular shape, but with a more decided tendency to assume the circular form than those of measles. In a given case there is generally some uniformity in the matter of size—either the papules are for the most part of the larger size, or they are nearly all small. Still greater differences of size have been described, however, papules of one-third of an inch in diameter having not infrequently been encountered.

Generally the skin between the papules presents a perfectly healthy appearance, although careful investigation will occasionally reveal the existence of minute fine lines or processes connecting adjoining papules. A general erythematous redness of the skin has also been noticed. Confluence of the papules is very rare, though not uniformly absent.

Vesicles have been observed, but this has clearly been a coincidence, and not at all a part of the ordinary course of the eruption. They are probably found quite as often with measles, and in either case must be regarded as anomalous. The eruption has been observed to suddenly disappear, and after a short time to reappear; and unusual warmth, as from heavy clothing, renders it more distinctly visible. A certain amount of itching is often present, though not severe, and the heat and burning, which are a source of discomfort in scarlatina and measles, are not at all pronounced in Rötheln.

To sum up the characteristics of the eruption, we may make a division of the cases into two classes, which correspond with the descriptions formerly given of rubeoloid Rötheln on the one hand, and scarlatinoid on the other. In each variety the resemblance to the other disease, as far as the eruption is concerned, may be very close—often sufficiently so to render the diagnosis extremely uncertain, if the other points of history and symptomatology be not carefully considered.

In the first class of cases, comprising the greater number, the papules are of larger size, perhaps abundant enough to be considered confluent, of somewhat irregular shape, pale rose color, and raised considerably above the skin. It will be seen that this state of affairs can obtain with measles quite as well as with Rötheln.

In the second class the papules are smaller, more circular in shape, less elevated above the skin, of darker hue, much more numerous, and sometimes very closely aggregated, so as to give the punctated appearance alluded to. If this be the appearance, there may easily be nothing in the eruption by which to discriminate it from a scarlatinal rash at the onset or during the first day of the disease. A fully developed rash of scarlatina is continuous, leaving no skin normal in appearance between the eruptive spots; and in Rötheln the papules are distinctly separated from each other.

Taking, therefore, an extreme case of either variety, it will be found that other points in symptomatology and history are requisite, and possibly a delay for one or two days may be necessary, in order definitely to eliminate doubt in the diagnosis.

Desquamation.—Desquamation is the mode, or perhaps a better term would be the accompaniment, of the termination of the eruption, beginning on the second or third day. It is furfuraceous in character, never occurring in large scales or pieces of skin as in scarlatina. It is fine, and in this resembles more the desquamation of measles. It is much less decided than in scarlatina, and is often so slight in amount as to be perceived only on very careful inspection, and frequently passes unnoticed by either the patient or the physician. Many writers on the subject do not make mention of the process, and frequently the statement is made that it is not a part of the clinical history of the disease. The writer cannot contradict this, though holding the view that it is present in some degree in all cases. As fading of the color of the eruption very quickly sets in, and is progressive until its final disappearance, the desquamation is the accompaniment of this.

The desquamation is not to be found affecting at one time the entire surface which has presented the eruption. It follows the appearance of the rash, and, consequently, is visible on one part of the surface before it is on another. Furthermore, it does not take place over the entire affected surface—much of the eruption fades away without desquamation, and the latter is to be searched for about the trunk, legs, and arms especially. The face and extremities usually escape. In this there is another point of resemblance to measles.

Following the customary division of the eruptive fevers into stages, we may consider the stage of desquamation, fading, or decline, to occupy the time from the second day of the eruption to the end of the disease. But it must be borne in mind that the line of division between these two stages, *i.e.*, of eruption and of desquamation, is much less distinctly marked than in scarlatina or measles.

Occasionally a faint staining or pigmentation has remained for several days after the disappearance of the rash proper.

Symptoms other than the Eruption.—These have been in part considered under the head of premonitory symptoms, or those presenting themselves in the stage of invasion, and are, in great part, simple continuations of them. They are found, like those of scarlatina and measles, to have special reference to the mucous membranes of the nose, throat, and conjunctiva, together with more or less disturbance of the digestive functions. The inflammatory condition of the throat and tonsils, which is the most frequent of these symptoms, varies greatly in degree, and, beginning in the stage of invasion, persists up to the time when the rash has reached its height, and then subsides with the disappearance of the rash. Slight cough sometimes persists a few days longer. The conjunctival irritation and the œdematous swelling of the eyelids are not often pronounced, and follow much the same course as the throat-symptoms.

The nausea, which presents itself often enough to call for special mention, is generally noticeable only until the rash has developed.

The tongue is commonly coated, but does not at all present the appearance of the strawberry tongue of scarlatina. All these symptoms, when present at all, are of decidedly milder character than they are in scarlatina and measles.

The temperature range has been referred to as being liable to differences in epidemics and in individual cases. As a general rule, the rise is much less than that of the two other diseases. An elevation of one to two degrees—to 99½° or 100½° F.—is what we may look for, persisting about three days, and in the given case not presenting

the fluctuations characteristic of measles, but remaining at the same level until its final subsidence.

The pulse and respirations are accelerated in proportion to the rise of temperature.

In general a severe case presents a greater variety of these symptoms, as well as a greater severity, and a mild case, absence, or nearly such, of them.

The single phenomenon, over and above the eruption, which is characteristic, and one might almost say pathognomonic, of Rötheln, is the enlargement of the post-cervical and sub-occipital lymphatic glands. Probably in no case is it found wanting. This occurs at the onset of the disease, and therefore, as stated, may not infrequently be discovered before the appearance of the eruption. The number of glands affected varies from one or two up to seven or eight. Search should be made for them from the occiput down to the level of the shoulders, and toward the middle of the neck rather than at the sides or near the angle of the jaw. In scarlatina, diphtheria, and other throat affections, the glands which present enlargement are those at the angle of, as well as beneath, the lower jaw. In such instances the swelling seems to be proportionate to the severity of the throat inflammation, and to be associated with it, as in adenitis in the neighborhood of inflammation elsewhere in the body. But the adenitis of Rötheln cannot be so explained, as it is found equally in the cases with considerable sore-throat, and in those with none. Therefore it should be regarded as a distinct phenomenon of the disease, and not as an accessory.

Associated with the enlargement is stiffness of the neck, and pain on moving the head, in some degree, though never very severe. The enlargement itself varies, the glands being of about the size of a split pea or bean; suppuration does not occur, and the swelling and pain subside with the disappearance of the eruption. Occasionally a single gland will remain perceptibly enlarged, though painless, for an indefinite length of time.

Valuable as this point is, there are yet sources of error, and glandular enlargement from other causes must be excluded.

The condition which we recognize as struma, indicating the general condition of ill-health due to bad hygienic surroundings and malnutrition, has, as a prominent feature, general glandular enlargement, perceptible in the groins, axillæ, etc., as well as in the neck; and syphilis may present the same condition. Accordingly, search should be made in those other localities before assigning a cervical adenitis to an oncoming, or present, attack of Rötheln. Enlargement of the glands at the angle of the jaw is to be attributed to other causes. Children with eczema capitis have, almost always, large lymphatic glands in the neck.

During an epidemic of measles in 1886, the writer made investigation with special reference to this point, and found that in 24 out of 29 cases an enlargement of glands exactly similar to that of Rötheln was present, and constituted a prominent feature of the cases. This was evidently a peculiarity of that epidemic, as the writer has neither before nor since found it to be the case, except in isolated instances. Griffith states that he has not infrequently found it. Care was taken to render the diagnosis of measles certain, and mention is made of this point here to show that the adenitis characteristic of Rötheln is not absolutely pathognomonic, and will not in itself suffice for differential diagnosis from measles.

Non-identity with Measles and Scarlatina.—The writer has, of necessity, made frequent mention of Rötheln as contrasted with scarlatina and measles, and the reasons for considering it to be an independent disease must now be considered. There are still some who consider it a hybrid, consisting of elements drawn from both those diseases, and being intermediate in character between them. This position is scarcely tenable, and is not supported by clinical facts; since the greater number of cases, though having points in common with both, present, each one, strong points of resemblance to one or the other of the two affections, and not to both at the same time. That is, any single case is either decidedly scarlatinoid or decidedly rubeoloid; and the differential diagnosis lies between two and not three diseases. Furthermore, hybrids are not at all common, and analogy is opposed to this view. Generally, what is called a hybrid can be resolved into its elements, and may be pronounced a conjunction of two or more disease-conditions. Undoubtedly scarlatina and measles may be found coexisting in the same individual, or following each other so closely as to overlap, the inmates of a household being exposed to and contracting both diseases at the same time, or in rapid succession. These cases, however, present the phenomena of both diseases in such a manner and degree as to exclude uncertainty in the diagnosis, and they bear no closer resemblance to Rötheln than any single well-pronounced case of either disease.

The question of its identity with one or the other of these diseases calls for more careful consideration.

There are but few who believe Rötheln to be identical with scarlatina, but many consider it of the same nature as measles. In a scarlatinoid case the principal points in common are: the short period of invasion, the existence of some sore-throat, and the fine punctate appearance of the rash at first. Rötheln is liable to be confounded only with a very mild case of scarlatina; for the vomiting, high fever, pronounced sore-throat, and characteristic tongue of average scarlatina are not encountered in the former disease. The points of difference are most prominent in the longer duration of the eruption in scarlatina, its greater uniformity, its macular character, the nature of the desquamation, and the presence of sequelæ which do not occur in Rötheln. In addition to which the adenitis of Rötheln is not to be found in the other disease.

As to measles, the similarity also exists in a certain proportion of cases of mild character. The symptoms which may be common to both are the rose color and papular character of the rash, the shorter duration of the period of eruption, the fine desquamation, and possibly the adenitis. The main point of difference is the presence, in measles, of two or three days of fever, with catarrhal inflammation of the respiratory mucous membranes, uniformly preceding the eruption. The sequelæ of measles, also, are not to be expected in Rötheln.

As stated, these resemblances are encountered only in extreme cases. Average cases of each disease have special characteristics sufficient to clear away doubt; and the differences just enumerated go far toward proving non-identity in either direction. But the strongest reason for believing in the individual nature of Rötheln—constituting, indeed, a conclusive proof—is that no mutual protection is afforded. That both scarlatina and measles are, if the expression be allowed, auto-prophylactic, has been proven by thousands of observations. Second attacks of scarlatina are so rare as to be curiosities in the history of medicine; and with measles, although the rule is not so free from exceptions, yet a second attack is a very infrequent occurrence. This rule applies to Rötheln. As yet there are few, if any, authentic records of second attacks. But when the question of mutual protection, which would be a *sine qua non* to the supposition of identity, is considered, the most conclusive evidence of its absence is presented.

Of J. Lewis Smith's 48 cases, 19 had had measles, and 1 contracted the disease subsequently. Of Shuttleworth's 30 cases, more than half had had measles, and 4 scarlatina. In one case the patient had measles five months, and scarlatina one month, before. In 13 of the cases, where subsequent observation was possible, 7 contracted measles, and 6 scarlatina, after the lapse of a few years. Goodhart observed that 39 out of 63 cases had had measles.

Instances might be multiplied to a very large number, but it is unnecessary; for the non-existence of mutual protection is too well established to admit of doubt. There is, however, another aspect of this question, or, rather, another explanation of the facts, which has been presented with considerable appearance of probability. It is that Rötheln is simply the modification of measles presented in second attacks, bearing the same relative

position that varioloid does to small-pox. There are two reasons for regarding this position as untenable. The first is, that pronounced attacks of true measles have, in a large number of instances, followed, and not preceded, Rötheln, and these cases have presented no modification in kind or severity of the symptoms which go to make up the clinical history of measles. This applies with equal force to scarlatina. The second reason is, that in the individuals who have been the subjects of second attacks of measles, the symptoms have been as uniform and pronounced as in the first.

On the contrary, a much closer analogy can be traced between small-pox and varicella on the one hand, and measles and Rötheln on the other. The ratio is much the same in regard to corresponding severity, and in similarity of appearance of the eruption.

The final separation, in the minds of medical men, of the former pair from each other, was beset by the same uncertainties as that of the latter.

Another fact of significance is that Rötheln occurs in epidemics, when neither scarlatina nor measles is prevailing; and, in the same epidemic, most of the cases will be rubeoloid, and a smaller number scarlatinoid.

Text-book descriptions of measles commonly refer to a variety of the disease under the designation of "rubeola sine catarrho," this name indicating a condition in which there is fever, with an eruption similar to that of ordinary measles, and at the same time absence of the inflammation of the respiratory apparatus. Perhaps it is fair to consider these as cases of Rötheln; and a significant observation made by Watson, in his "Practice of Medicine," gives support to this view. He says: "It is observed that rubeola sine catarrho confers no protection against recurrence—is commonly succeeded by an attack of measles in its true form." Meigs and Pepper make the same observation as to their experience.

To summarize, the points demonstrating the non-identity of Rötheln with measles or scarlatina are:

1. The difference in clinical history.
2. Absence of mutual protection.
3. Absence of modification in second attacks of those two diseases.
4. Occurrence of epidemics while the other two are not prevailing.
5. In any epidemic, resemblance of some of the cases to one, and of some to the other, of the two diseases.

A further differentiation of the two varieties into two distinct diseases is possible; but it would be a refinement almost beyond our present powers of observation.

Diagnosis.—The diagnosis is principally made by process of exclusion, because, at the outset, the presence of scarlatina or measles is generally suspected. From scarlatina at the outset, or in the first day or two of sickness, in certain mild cases, the points of difference are: In Rötheln, the absence of, or presence in a milder degree, of sore-throat; the absence of the strawberry tongue, and the existence of a whitish coating if any change be present; the absence of continuity of the eruption; and the presence of post-cervical adenitis, the glands at the angle of the jaw being unaffected. After the lapse of two or three days the course of the eruption in Rötheln is to reach its maximum and begin to disappear quickly, and the desquamation, when perceptible, is fine, and not in flakes or patches of some size.

Pronounced cases of scarlatina do not resemble Rötheln sufficiently to render the diagnosis uncertain.

From measles the discrimination is to be based mainly on the absence of the stage of fever with catarrh preceding the eruption, or its very mild character and shorter duration. The cervical adenitis has much weight, though it is not absolutely conclusive. Though the rash may very closely resemble that of measles, yet the papules are less elevated, smaller, less aggregated, less decidedly rose-colored, and run their course more quickly —desquamation setting in two or three days before it would be likely to occur in measles.

Subjoined is a comparative table of these three diseases in their different stages, giving also the average duration of each stage.

Rötheln.	Scarlatina.	Measles.
	Stage I.—Incubation.	
Duration, six to twenty-one days.	Two to fourteen days.	Twelve to fifteen days.
Inconstant.	.	Constant.
	Stage II.—Invasion.	
One day or less.	Less than one day.	Two to four days.
Often absent.	Never absent.	Never absent.
Malaise, slight.	Vomiting.	
Sore-throat and lachrymation.	Decided sore-throat.	Drowsiness, cough, coryza, conjunctivitis, photophobia.
Cervical adenitis.		
Temperature, 99°–100°.	Temperature, 103°+.	Temperature, 102°+.
	Stage III.—Eruption.	
Three days.	Six to eight days.	Four to five days.
Begins on face or chest.	Begins on chest.	Begins on face.
Papular, slightly.	Macular.	Papular, decidedly.
Pale rose, or darker and brownish.	Deep-red scarlet.	Rose.
Not continuous.	Continuous.	Not continuous.
Ceases spreading in one or two days.	Ceases spreading in three or four days.	Ceases spreading in two or three days.
No stationary period.	Stationary period of two to three days.	Stationary period of two to three days.
Burning or itching, slight.	Burning, often great.	Burning and itching, decided.
	Stage IV.—Desquamation.	
Very slight and fine.	In scales of quite large size.	Furfuraceous, and often not pronounced.
Overlaps stage of eruption.	Preceded by stationary period.	Preceded by stationary period.
Lasts two or three days.	Lasts ten days, and sometimes longer.	Lasts about four days.
		Leaves dull colored stains.
	Complications.	
	Acute form of Bright's disease.	Bronchitis.
None characteristic.	Rheumatism.	Pneumonia.
	Otorrhœa, and necrosis of temporal bone.	Tuberculosis.
		Inflammation of the intestines.

In addition to these other exanthemata, certain simple skin diseases must be considered in the diagnosis. Sometimes the eruption of miliaria papulosa (prickly heat) resembles that of Rötheln; but it occurs in well-defined patches of several inches in diameter, is associated with unusual sweating, and lasts many days longer. Also, there are no febrile and constitutional symptoms accompanying miliaria, and the itching is usually great.

The most careful investigation possible into the origin or sources of contagion should be made; and in cases of doubt a positive diagnosis should be withheld for one or two days. It may be advisable to explain the uncertainties, and to adopt the precautions as to isolation, etc., necessary in scarlatina.

Complications.—Complications or sequelæ characteristic of the disease do not exist. A condition of transient albuminuria is spoken of, but it is not indicative of renal disease. After the rash disappears we may expect to find the usual condition of health present. The prognosis is therefore good.

Treatment.—Because of the mildness of the disease there is generally nothing called for in the matter of medication—simple restriction of diet and avoidance of exposure during the continuance of the elevated temperature being all that is necessary. Practically the interest and importance attaching to Rötheln lie in recognizing it as a separate disease, and in the exclusion of the more serious affections, scarlatina and measles.

Bibliography.—Besides the treatises of Meigs and Pepper, J. Lewis Smith, Vogel, Day, Goodhart, Eustace Smith, and Ellis, on "Diseases of Children;" those of Bristowe, Bartholow, Loomis, Aitkin, and Flint, on the "Practice of Medicine;" and Da Costa's work on "Medical Diagnosis," the following articles may be mentioned: Hardaway, in "Pepper's System of Medicine;" Hartshorne, in "Reynolds's System of Medicine;" Thomas, in "Ziemssen's Cyclopædia;" Cheadle, Shuttleworth, and Squire, in the "Trans. Internat. Med. Cong.," 1881; Griffith, in the N. Y. *Medical Record*, July 2 and 9, 1887; Edwards, in the *Am. Jour. Med. Sci.*, 1884; Jones, *Boston Med. Journ.*, 1881; Sholl, *Med. and Surg. Reporter*, 1882; T. D. Swift, *N. Y. Medical Journal*, November 27, 1886; Harrison, *Am. Journ. Obstet.*, 1885; Duck-

worth, Erskine, and Gowers, in London *Lancet*, 1880; Dukes, ibid., 1881; Yonge-Smith, ibid., 1883 and 1886; Strover and Jaccoud, ibid., 1886; Shuttleworth, Brown, Burnie, Davis, Rooke, and Wilson, in *Brit. Med. Journal*, 1880; Byers and Sadell, ibid., 1881; Lawrence, ibid., 1882; Shackelton and Cullingworth, ibid., 1883; McLeod, ibid., 1885; and Ryle, ibid., 1886.

Thomas D. Swift.

ROHITSCH-SAUERBRUNN, an Austrian spa, lies in a well-protected valley, near Poltschach, Steiermark, at an elevation of about eight hundred feet above sea-level. It contains seven medicinal springs, the waters of two of which only, the Moritzquelle and the Tempelbrunnen, are used internally. The following is the analysis of the Tempelbrunnen. Each litre contains:

	Grammes.
Sodium chloride	0.094
Sodium sulphate	2.024
Sodium bicarbonate	1.075
Calcium bicarbonate	2.226
Magnesium bicarbonate	1.970
Ferrous bicarbonate	0.011
Organic matters, etc	0.025
Total	7.425

There is a variable amount of free carbonic acid gas.

The waters of Rohitsch are employed in the treatment of chronic catarrhal affections of the respiratory and digestive systems, corpulence, malarial cachexia, and passive congestions of the abdominal viscera.

The climate is mild. The season extends from the first of May to the middle of September. *T. L. S.*

ROSEMARY (*Rosmarinus*, U. S. Ph.; *Romarin*, Codex Med.), *Rosmarinus officinalis* Linn.; Order, *Labiatæ.* This is a fragrant, evergreen shrub, from two to four feet high, with numerous grayish-brown branches. Twigs square, gray, covered with stellate hairs. Leaves from one-half to one inch or more long, thick, leathery, linear, blunt, with revolute margins, entire, dark green and shining above, covered with white stellate hairs beneath. Flowers axillary, in pairs, half an inch or so long, pale lilac; calyx, two-lipped; corolla also labiate, the upper lip bifid, the lower of three diverging lobes, the middle one of which is much the largest and deeply concave. Stamens four, the two upper rudimentary. Style long, ovary of four, nearly separate, rounded carpels. Fruit, four subglobose achenes. Rosemary is a native of the Mediterranean region (Southern Europe, Asia Minor, Northern Africa, etc.). It is also an old and widely cultivated garden-plant. The pungently aromatic leaves are officinal.

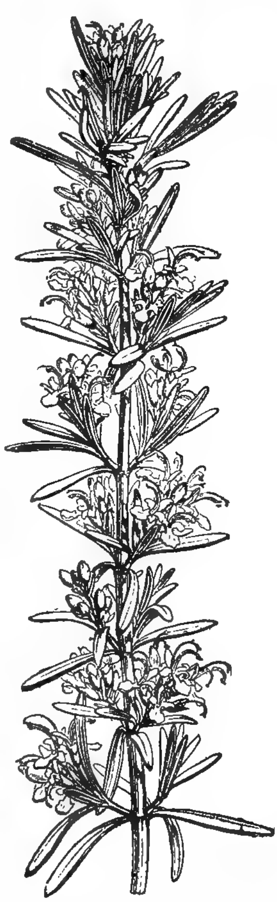

Fig. 3347.—Rosmarinus Officinalis; flowering branch. (Baillon.)

The principal constituent of Rosemary is the *essential oil*, a composite substance consisting of two or more hydrocarbons and a stearoptene. It is "a colorless or yellowish liquid, having the characteristic pungent odor of Rosemary, a warm, somewhat camphoraceous taste, and a neutral or faintly acid reaction. Sp. gr. about 0.900. It is readily soluble in alcohol."

This plant has the general aromatic properties of the rest of the order, but from its less agreeable taste is not so often given internally as the mints proper. Its pleasant odor, on the other hand, makes it, like Thyme, Patchouly, etc., a pleasant addition to liniments and cosmetics. Rosemary leaves are one of the ingredients of the obsolete Aromatic Wine (*Vinum Aromaticum*, U. S. Ph.), of which they comprise one per cent. The oil constitutes one per cent. of Soap Liniment, two per mille of Compound Tincture of Lavender, and eight of the officinal Cologne Water.

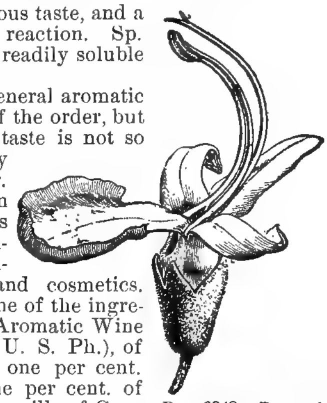

Fig. 3348.—Rosmarinus Officinalis; flower. (Baillon.)

Allied Plants, etc.—See Peppermint.

W. P. Bolles.

ROSES. These beautiful flowers contribute far more to man's pleasure than to his necessities. The genus *Rosa* gives the name to the great order *Rosaceæ*, and is the type of one of its divisions. It contains numerous not well-defined species of upright, climbing, or sprawling, mostly prickly, shrubs, with odd pinnate, conspicuously stipulate leaves, and terminal or clustered, showy, sweet-scented flowers. The floral envelopes and stamens are borne up on the thickened rim of a deep, vase-like, hollow receptacle, whose inner surface is covered with the numerous one-ovuled pistils. This receptacle, with its enclosed ovaries and crowned by the persistent calyx, ripens to a sourish-sweet fruit (rose hips). Calyx mostly five-parted; petals in single varieties mostly five: stamens very numerous, pistils moderately so. Some of the more familiar species follow:

R. lutea Mill. (*R. Eglanteria*), Eglantine Rose; Yellow Rose, with solitary large, handsome, yellow flowers. Southern Europe.

R. cinnamomea Linn., Cinnamon Rose.

R. canina Linn., the Dog Rose, or common Wild Rose, has stiff, compressed, recurved prickles serrate or lobed, reflexed sepals, a rounded, ovoid, scarlet, shining fruit, and clustered pink flowers. A common denizen of by-ways and hedges in most parts of Europe. The "Hips" (*Cynorrhodon*, Codex Med.), when fully ripe, and, preferably, touched by the frost, make a rather poor but edible kind of fruit, which in Southern Europe is made into jams and sweet sauces. They contain *citric* and *malic acids* and their salts, *sugar*, and a large amount of *gum*. A confection of rose hips is still a little used abroad as a vehicle. The galls produced upon this rose were also formerly used. Its name is said to have been derived from reputed value in dog-bites.

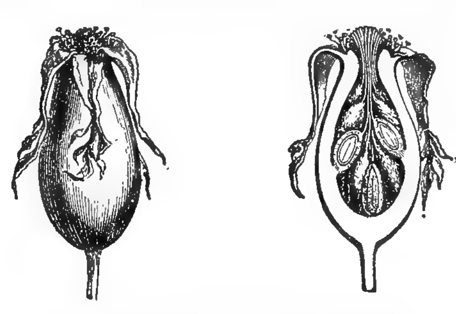

Fig. 3349.—Dog Rose Hips; about natural size. (Baillon.)

R. rubiginosa Linn., and *R. micrantha* Smith, are the

large and small-flowered sweetbriers easily recognized by their very fragrant leaves and stems.

R. Gallica Linn., the Provins or Red Rose has creeping rhizomes which send up a colony of rather short (two to four feet) stems. These are armed with numerous short, straight, weak prickles, and a few longer ones, and are covered with bristly hairs. The leaves are also somewhat hairy beneath, and blue-green in color. The flowers grow singly or in twos. They have a glandular, hairy receptacle and calyx, dark-red petals, and a nearly globular fruit. A native of Central Europe, but long under cultivation, for medicine as well as ornament. The petals, pulled or cut away, just before expanding, and dried, are officinal (*Rosa Gallica*, U. S. Ph.; *Rosæ Gallicæ Petala*, Br. Ph.; *Rose rouge ou Rose de Provins*, Codex Med.). When carefully dried they have a fine purple-red color and fine fragrance. They usually remain in the same cone-shaped bunches in which they were plucked, and unless cut away rather high, show whitish or yellowish claws. They contain a minute quantity of *essential oil*, some *fat*, *quercitrin*, a little *gallic* and *tannic* acids, and a beautiful *coloring matter*. As may be inferred, they have no active properties, and are only used for their color or as a vehicle.

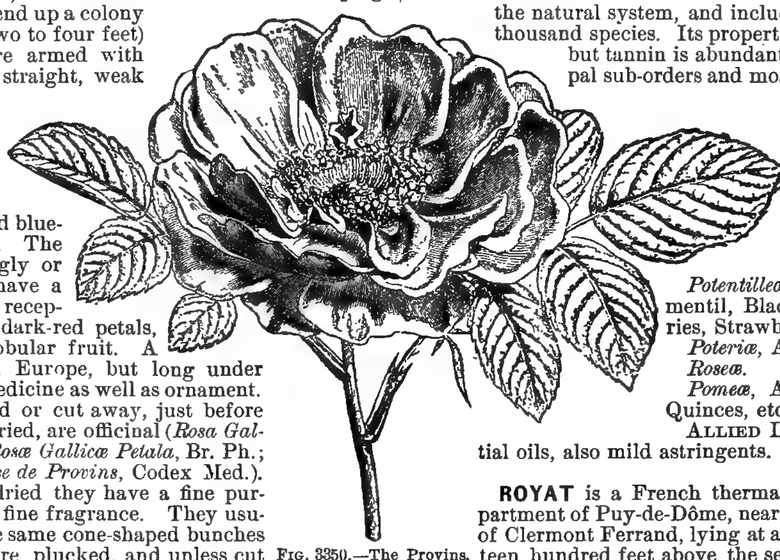

FIG. 3350.—The Provins, or Red Rose, in full bloom. (Baillon.)

The Pharmacopœia has the following preparations: Confection (*Confectio Rosæ*)—

Red Rose	8 parts.
Sugar	64 "
Clarified Honey	12 "
Rose Water	16 "

rubbed and beaten to a smooth mass, suitable for pills; Fluid Extract (*Extractum Rosæ Fluidum*); Honey (*Mel Rosæ*), strength, $\frac{8}{100}$; Syrup (*Syrupus Rosæ*), strength, $\frac{1}{10}$. It is also employed in making the Pills of Aloes and Mastich. Red Rose petals are collected in England, France, and Belgium.

Rosa centifolia Linn., possibly a variety of the above, is the parent stock of numerous fragrant, very full-flowered varieties. It has large, hooked prickles, and drooping, generally double, pale-colored flowers. A native of the Orient, but cultivated from time immemorial. The Moss Rose is one of its almost innumerable forms. Pale, Hundred-leaved, or Cabbage Rose petals (*Rosa Centifolia*, U. S. Ph.; *Rosæ Centifoliæ Petala*, Br. Ph.; *Rose à cent feuilles*, Codex Med.; *Flores Rosæ*, Ph. G.), collected and carefully dried after the expansion of the flowers, are, more or less, heart-shaped or abovate, have a pink color, a sweetish, slightly astringent taste, and a delicious rose-like odor. When fresh they are a source of Rose Water (*Aqua Rosæ*, U. S. Ph.); when dry, used for various pleasant but unimportant purposes, but mostly as a perfume.

R. damascena Mill (*Rose de Damas ou des quatre saisons*, Codex Med.). The Damask Rose, another Eastern species, has large, hooked prickles and fine sweet flowers. It is one of the sources, at least, of the Oil of Rose (*Oleum Rosæ*, U. S. Ph., Ph. G., etc.). The only important constituent of this rose and some others is the minute quantity of oil that they contain. This is separated by distillation and in great demand for perfumery. It contains a hydrocarbon of little odor, and several fragrant stearoptenes that cause the whole oil to congeal at a moderately low temperature (50° F.).

Besides the above, the Tea Rose, *R. Indica*, and numerous others are cultivated for ornament, and several American ones have begun to be. All the roses become double in the garden; most of them hybridize readily.

ALLIED PLANTS.—The order is one of the largest in the natural system, and includes more than one thousand species. Its properties are very diverse, but tannin is abundant in it. The principal sub-orders and most useful species are as follows:

Pruneæ, Almonds, Peaches, Plums, etc. (see ALMONDS).

Spiræeæ, Spiræas, etc.; Hardhock, Gillenia, etc.

Potentilleæ, Potentillas, Tormentil, Blackberries, Raspberries, Strawberries.

Poteriæ, Agrimony, Koosso.

Roseæ.

Pomeæ, Apples, Pears, Quinces, etc.

ALLIED DRUGS.—The essential oils, also mild astringents. *W. P. Bolles.*

ROYAT is a French thermal station in the department of Puy-de-Dôme, near the railroad station of Clermont Ferrand, lying at an elevation of fourteen hundred feet above the sea. There are five springs.

The following are the analyses of the two which are the richest in saline constituents, given in grammes per litre.

	Source Principale.	Source Saint-Mart.
Potassium bicarbonate	0.425	0.365
Calcium bicarbonate	1.000	0.953
Magnesium bicarbonate	0.677	0.611
Ferrous bicarbonate	0.040	0.042
Manganous bicarbonate	trace	trace
Sodium bicarbonate	1.349	0.421
Sodium sulphate	0.183	0.163
Sodium phosphate	0.018	0.007
Sodium arseniate	trace	trace
Sodium chloride	1.728	1.682
Silicic acid	0.156	0.102
Total	5.586	4.346

There is a considerable amount of free carbonic acid gas. The temperature of the different springs ranges from 82° to 95° F.

The waters of Royat are taken internally, and also employed in baths of various kinds. The whey- and grape-cures are also used to some extent. The diseases in the treatment of which the Royat waters are recommended are chlorosis and anæmia, debility following convalescence from acute diseases, vesical catarrh, muscular rheumatism, and certain forms of eczema. A course of treatment lasts from two to four weeks. The season extends from June to the middle of September.

T. L. S.

RUBINAT-CONDAL. This is the name of a natural mineral water recently introduced into this country, which, it is claimed, is one of the best of the natural saline aperients. The following is given as its composition, according to an analysis of Dr. Canudas y Salada. One litre contains:

	Grammes.
Magnesium sulphate	3.172
Potassium sulphate	0.228
Calcium sulphate	1.887
Sodium sulphate	93.230
Sodium chloride	1.990
Silica, alumina, and ferric oxide	0.036
Loss	0.017
Total	100.560

The spring from which this water is taken is situated in the Spanish Pyrenees, near Cervera, in the province of Lerida. As it has been so recently introduced to the notice of the medical profession in America, it is not

possible to speak with greater precision concerning the merits of the water. *T. L. S.*

RUE, OIL OF (*Oleum Rutæ,* U. S. Ph., Br. Ph.; *Rue,* Codex Med. [the flowering plant]). The essential oil of *Ruta graveolens* Linn.; Order, *Rutaceæ.* This is a perennial herbaceous or partly woody plant, two or three feet in height. It has pale green, cylindrical, branching stems, alternate, smooth, light-green, glandular-dotted leaves; the lower twice or three times pinnate, the intermediate once or twice pinnate, the uppermost simple. Divisions wedge-shaped, rounded, or blunt at the extremity. Flowers in a terminal corymb, with the parts in fours or fives; stamens twice as many; sepals small, pointed; petals large (one-half inch long), rounded, and hooded at the ends, narrow below, greenish-yellow. Pistil supported on a thick, fleshy disk; style single, ovary four- or five-lobed, with numerous ovules. Fruit a dry, dehiscent capsule. Rue is a native of Southern Europe, the Levant, etc., and is also cultivated; it has a strong, disagreeable odor, and a bitter, sharp taste. The oil only is officinal here.

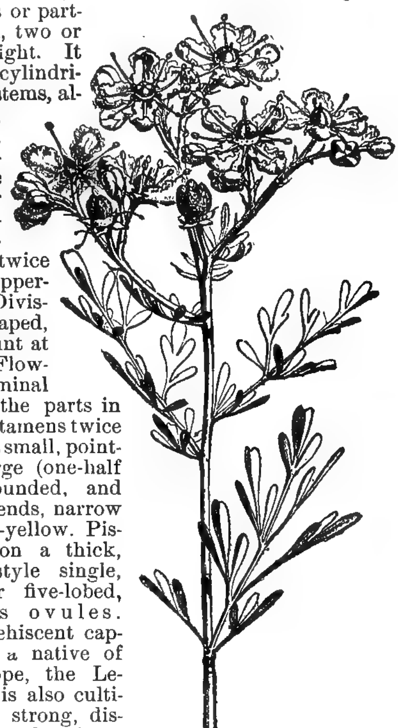

Fig. 3351.—Flowering Branch of Rue. (Baillon.)

Oil of Rue is obtained from the whole plant by distillation, the yield being about one-fourth of one per cent. It is "a colorless or greenish-yellow liquid, of a characteristic aromatic odor, a pungent, bitterish taste, and a neutral reaction. Specific gravity about 0.880. It is soluble in an equal weight of alcohol" (U. S. Ph.). Oil of Rue consists of a hydrocarbon and an oxygenated portion, the latter yielding pelargonic acid by decomposition. The leaves of Rue also yield a crystalline, neutral substance called *rutin,* which is found besides in several other plants. It is not active.

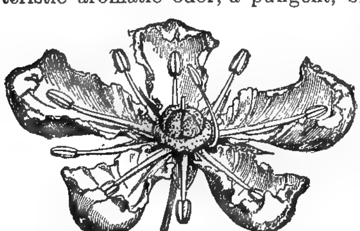

Fig. 3352.—Rue, the Flower. (Baillon.)

Oil of Rue is one of the more deleterious of the essential oils. Like turpentine, tansy, juniper, and others, it is externally quite irritating, and on this account is used in liniments and plasters. Given internally, it is an anthelmintic, "antispasmodic," and "emmenagogue," according to the older authorities, and was used in amenorrhœa, hysteria, and epilepsy; but it is scarcely given internally now. Dose from two to five drops.

Fig. 3353.—Fruit of Rue. (Baillon.)

Allied Plants.—The genus comprises about forty plants of Europe and Asia, none of the others of economic importance. The order is a large one, of mostly tropical plants, nearly all fragrant, and many of considerable importance in medicine, etc., as the following selections will show:

Ruta graveolens Linn., Rue.
Dictamnus albus Linn., Fraxinella.
Cusparia trifoliata Engl., Angustura.
Pilocarpus, several species, Jaborandi, Pilocarpine.
Barosma, several species, Buchu.
Xanthoxylum fraxineum Willd., Prickly Ash.
Toddalia aculeata Pers., Lopez Root.
Citrus, several species; Oranges, Lemons, Bergamottes, etc.
Aegle Marmelos Correa, Bael.

Allied Drugs.—Oils of Tansy, Cedar, Juniper, Turpentine, etc., have physiological properties somewhat like that of Rue. *W. P. Bolles.*

RUSCUS ACULEATUS Linn. (*Petit Houx ou Fragon épineux,* Codex Med.), a singular perennial, half-shrubby, liliaceous plant, with minute bract-like leaves and flattened leaf-like stems in their axes, looking almost exactly like leafy foliage excepting when the little flowers appear from the middle of their apparently upper surfaces. Its root is laxative, but scarcely used now.

W. P. Bolles.

Fig. 3354.—Ruscus Aculeatus; flowering branch. (Baillon.)

RYE (*Seigle,* Codex Med.), *Secale cereale* Linn. (*Triticum cereale* Archers); Order, *Gramineæ.* This important grain, standing nearer in some respects to wheat than the others, has, like them, been so long in cultivation as to have lost its early ancestry, and is not known wild. It will grow in colder latitudes than wheat, and on this account is the principal breadstuff in some of the northern parts of Europe. It is also extensively grown in the

northern States of this country and in British America. Eastern Asia is supposed to be its original home. Rye-flour is darker, grayer in color than that of wheat, and has a characteristic odor and taste. It is more laxative than wheat-flour, and makes a dark-colored, sweetish-sour bread (*Schwarzbrod*) very widely used on the continent of Europe, and among the Germans in this country. Rye consists of nearly sixty per cent. of *starch*, ten of *nitrogenous substances*, two of *fat*, four of *sugar* (synanthrose), seven or eight of *gum*, *dextrin*, etc., besides ten or more of water, and one or two of ash.

FIG. 3355.—Rye. 1, Inflorescence; 2, entire plant; 3, spikelets; 4, flower; 5, the same, after removal of the glumes; 6, grain. (Baillon.)

Rye is in no sense a medicine, but it has been with some people a favorite poultice material. It is also interesting as the "host" upon which ergot grows.

ALLIED PLANTS, ETC.—See STARCH. *W. P. Bolles.*

SACRO-ILIAC DISEASE. Syn., Sacro-coxitis (Hueter), Sacrarthrocace, Sacro-coxalgie. The ilio-sacral joint resembles the other articulations of the body in its anatomical structure, but differs from most of them chiefly in the limited amount of motion of which it is capable. It may be compared with the intervertebral articulations in this respect. Although this joint is called upon to support the weight of the trunk and upper extremities, in both the standing and sitting postures, it is, nevertheless, owing to the slight degree of motion possible, not so often the seat of traumatic lesions as might *à priori* be supposed. Yet it is probable that the joint more often feels the effect of slight traumatisms than is generally believed. The lumbar pains and backache experienced after long standing, walking, riding in a springless wagon over a rough road, or horseback exercise, are, in many cases, the result of slight injury, or tire, of the ilio-sacral articulation (Chauvel), although doubtless muscular strain is also often an important factor in their causation.

The joint is occasionally, though rarely, the seat of an acute inflammation, which runs its course rapidly, attended with high fever and suppuration, and which is apt to terminate in the death of the patient from exhaustion. The chronic form is much more often seen, though it is nevertheless comparatively rare. Chronic sacro-iliac disease is, however, notwithstanding the infrequency of its occurrence, and apart from its intrinsic importance, well worthy of careful study by reason of its liability to be mistaken for hip disease, spondylitis involving the lower segments of the spinal column, or other lesions of neighboring parts.

The lesions of sacro-iliac disease are similar to those accompanying chronic inflammation of other joints, for a description of which the reader is referred to the article entitled Joints, Chronic Diseases of, in the Appendix. There are three varieties usually described, viz., the tubercular, the puerperal (pyæmic), and the gonorrhœal or urethral. The possible occurrence of a fourth form, the syphilitic, may be admitted, but it is, at all events, extremely rare.

The tubercular form, which is by far the most common, begins usually as a fungoid synovitis, the morbid process extending later to the cartilage and bone; but occasionally the joint is invaded by the extension of a carious or necrotic process which had begun in the sacrum or ilium.

The disease is exceedingly rare in childhood, its period of greatest frequency being in early adult life. Men are more commonly its subjects than are women. In its etiology the tubercular form of sacro-iliac disease differs in no essential respect from a similar chronic arthritis occurring elsewhere. Chauvel asserts that the affection occurs with comparative frequency in young cavalry soldiers, and finds its exciting cause in the traumatism arising from the unwonted equestrian exercise. The etiology of the puerperal and gonorrhœal varieties is sufficiently indicated by the terms employed to designate them.

The symptoms of sacro-iliac disease are often obscure. They resemble closely those of Pott's disease of the lumbo-sacral region, or of morbus coxarius. Pain is a nearly constant symptom, though it varies much in degree, from a heavy, dull ache to an acute, agonizing pain, often increased beyond endurance by the slightest movement of the inflamed surfaces. Like the pain accompanying arthritis of other articulations, it is often intermittent and irregular in its exacerbations; it is aggravated by standing or sitting, but usually, though not always, relieved when the patient assumes the recumbent posture; it is apt, also, to be more severe at night than it is when the patient is at rest during the day. In severe cases the pain is increased by anything which causes movement of the articulation, even by sneezing or by the effort of defecation. Pressure over the sacrum, and any movement imparted to the innominate bone, as by approximation, separation, or twisting of the iliac crests, excites more or less pain; but gentle passive movements of the lower extremities, apart from direct upward impulses, usually cause no complaint if the pelvis be firmly held so as to prevent all movement at the ilio-sacral joint. There may be tenderness on pressure over the suspected joint, but this is not always

present. Sometimes it can be elicited by pressure on the anterior surface of the joint by means of the finger in the rectum. The pain is sometimes referred directly to the articulation affected, but may often be felt in the lumbar region, in the thigh, or even in the knee, and it may at times simulate sciatica so closely as to be mistaken for it.

Swelling is usually present at some stage of the disease, though this is not invariably the case. In the early stages, before an abscess has appeared, there may be a localized swelling in the neighborhood of the articulation, and at a later period the entire limb on the affected side may become œdematous. It is not rare, however, to encounter no appreciable swelling at any time during the course of the disease, except such as may be due to an abscess.

The appearance of an abscess is not uncommon, though suppuration is no more a necessary accompaniment of tubercular disease of the sacro-iliac joint than it is of a similar process occurring in other articulations. It is usually not until after the disease has existed for a considerable length of time that an abscess can be detected. The pus may present itself posteriorly over or near the articulation, sometimes forming a considerable tumor in the buttock, or it may, especially when it comes from the anterior portion of the joint, burrow in any direction and present itself as a cold abscess at some point more or less distant from its source. Thus it may open into the rectum, present itself as a tumor of the ischio-rectal fossa alongside the anus, appear in the back near the spine, or in the groin, or come to the surface on either the anterior or the posterior aspect of the thigh.

The temperature over the diseased articulation is elevated to a greater or less degree.

Atrophy of the muscles of the corresponding limb is invariably present, and usually in a very early stage of the disease, becoming more pronounced in proportion to the duration of the inflammatory process. The gluteal region is flattened, and the muscles are frequently soft to the touch and flabby.

The thigh may appear to be flexed and adducted, but in most cases, if not in all, this is not a real displacement, but is a consequence of malposition of the pelvis. The same is true of the apparent lengthening or shortening of the lower extremity, one or other of which, more commonly lengthening, is usually to be observed as a consequence of the obliquity of the pelvis. Sometimes there is a slight degree of outward rotation of the limb, so that the foot is turned more or less from the median plane of the body.

Limping is always present, though it may, at the outset of the disease, be intermittent or vary considerably in degree. The patient shows a hesitancy in allowing the weight of the body to rest on the affected side, and also moves the corresponding leg as little as possible. When it becomes necessary to transfer the weight to this side, the foot is placed carefully, the whole sole coming in contact with the ground as nearly as may be at the same moment, the heel and toe movement being avoided. The sound limb is then thrown rapidly forward, the patient meanwhile leaning heavily on his cane, and flexing the hip and knee slightly, as if to reduce as far as possible the force of the concussion. Then, when the body rests once more on the sound side, the other foot is raised slightly from the floor, and brought slowly and cautiously forward for a short distance, when it is again implanted evenly on the ground.

The position of the body when the patient is standing is also quite characteristic. In order to shift the centre of gravity as far as possible from the line of the diseased joint, the body is inclined strongly to the opposite side. The position may also afford relief, as has been suggested by Sayre, by making the weight of the limb on the affected side act as a traction force upon the inflamed articulation. This protective attitude may have its inconveniences, however, as lateral curvature of the spine may be produced as a result of its long continuance.

The diagnosis of a well-marked case of sacro-iliac disease is comparatively easy, if the points above detailed be borne in mind; but in an atypical case the recognition of the affection is sometimes exceedingly difficult, and mistakes in diagnosis are very easily made, unless the case is carefully studied.

The following table will bring out the differential points of sacro-iliac, hip, and spinal disease more clearly than could be done by a separate description of the symptoms of each one:

Sacro-iliac Disease.	Hip Disease.	Pott's Disease.
Is a rare disease.	Is a common disease.	Is not very common in the lumbo-sacral region.
Occurs usually in young adult males.	Occurs usually in childhood and in individuals of either sex.	Occurs more commonly in children, but is not rare in adults.
Motions of the hip are free.	Motion at the hip restricted in every direction by reflex muscular spasm.	Motion at the hip is free, except that extension and outward rotation are limited when there is psoas contraction.
The spine is not rigid, though it is often held stiff, as motion causes pain at the affected joint.	The spine is freely movable.	The spine is rigid at the seat of the lesion. In advanced stages there is more or less kyphosis.
Position is characteristic. Patient stands with the body inclined to the sound side.	Position is not characteristic, but varies with the stage of the disease and with the position of the thigh.	When loss of substance of the vertebral bodies has taken place, there is a forward inclination of the body.
The limb is apparently elongated (sometimes shortened), and there is not infrequently adduction.	The character of the deformity varies. There is real shortening, at least in the advanced stages.	The thigh may be flexed. Otherwise there is no malposition.
Cautious passive movements at the hip are painless. Severe pain is often excited by pushing together, separating, or twisting the wings of the ilia, or by pressure on the sacrum.	All movements of the hip cause pain. Motion of the sacro-iliac joint excites no complaint.	Movements of the hip painless. Pressure or the application of a hot sponge sometimes, though not always, causes pain.
The pain is usually localized near the affected joint, though it may be felt in the hip, knee, or thigh.	Pain is usually referred to the hip, knee, or middle portion of the thigh.	Pain is usually located in the back, but it may radiate down one or both thighs.
When a sinus is present, a flexible probe passes in the direction of the sacro-iliac joint.	Probe leads in the direction of the hip-joint.	Probing seldom aids, except in a negative way, in the diagnosis, as the abscess usually opens at a distance from the seat of the lesion.

In necrosis of the pelvic bones there may be a sinus leading in the direction of the ilio-sacral joint, but in uncomplicated cases there is no restriction to motion in any of the neighboring articulations, and no pain is excited by passive movements of these joints.

Sciatica may usually be easily discriminated by the fact that it is an affection of more advanced life than is sacro-iliac disease. The position of the patient is not characteristic; there is no deformity, except occasionally a slight degree of flexion of the hip and knee; motion of the suspected joints does not uniformly cause pain, and it is never restricted by reflex muscular spasm, as is the case in arthritis; and there is pain on pressure only over the course of the sciatic nerve.

Psoitis may simulate sacro-iliac disease, but it is more often mistaken for disease of the hip, or lower portion of the spine. The pain in this affection is increased by extension of the thigh, but is relieved by flexion, and all movements of the thigh which do not put the psoas muscle on the stretch are free. Pressing together, separating, and twisting the crests of the ilia, cause no pain. In psoitis there is flexion of the thigh, and if the body is inclined at all, it is toward the affected side rather than away from it. Finally, psoitis is attended with much more acute general symptoms than is uncomplicated sacro-iliac disease.

The possibility of neuromimetic joint disease should also be borne in mind in the endeavor to arrive at a correct diagnosis. For a general description of the nervous

mimicry of joint disease the reader is referred to the article on Neuromimesis, in vol. v. of this HANDBOOK.

Sacro-iliac disease runs a very slow and tedious course, being one of the most chronic of all chronic joint diseases. The patient is more or less incapacitated for any kind of work for a considerable length of time, since the sitting posture causes almost, if not quite, as much pain and inconvenience as does standing or walking. The prognosis, as regards life, is about the same as that in other forms of chronic joint diseases. Death may occur from exhaustion after prolonged suppuration, from renal complication, or from tubercular disease of other organs. Recovery, usually after a prolonged period of suffering, is, however, not uncommon.

The treatment of sacro-iliac disease, like that of other chronic joint affections, consists essentially in rest, traction on the inflamed articulation, and general tonic and supporting treatment. Hutchinson's method of the treatment of hip disease, by means of crutches and a high sole on the shoe on the sound side, answers better, in the writer's experience, for sacro-iliac disease than it does for the affection for which it was originally intended. For patients with sacro-iliac disease are older, as a rule, than hip patients; they understand the *rationale* of the method, and they are more careful not to discard the crutches and thump the foot down on the ground as soon as the disease begins to improve and the exquisite sensibility of the joint has disappeared. In certain cases, especially when the pain is very acute, the patient must be confined to the bed with a weight and pulley attached to the leg by means of a modified Buck's extension, such as is used in the application of an ordinary hip-splint.

Attention must, of course, be paid to the general health, for the patient has, at the best, to undergo a long siege; the disease is a debilitating one, and the sufferer must husband his strength to enable him to endure it.

Of local treatment by means of the injection of iodoform, or of calcium phosphate, as proposed and used by Kolischer, the writer is unable to speak from personal experience. But such methods, if as efficacious in the treatment of hip disease as is claimed, would seem to be particularly applicable to the treatment of tubercular disease of the ilio-sacral joint. *Thomas L. Stedman.*

SAFFRON (*Crocus*, U. S. Ph., Br. Ph., Ph.G.; *Safran*, Codex Med.). A perennial, colchicum-like herb, but with an inferior ovary. It arises from a flattened, fleshy corm, about three centimetres (one inch or more) in diameter, having a number of rootlets below and developing one or more buds upon its upper surface, which become new corms as the first one dies. It is covered with a few brown scales. From one or two of the buds a short stem arises, bearing a few long, linear, fleshy, shining green leaves. It ends near the surface of the ground in one or two flowers. These consist of an inferior ovary, of three cells, and a large, purple, bell-shaped perianth, with a very long (ten or fifteen centimetres), stem-like tube; divisions, six; stamens, three. This style is very long and slender, colorless excepting at the upper end, dividing finally into three long, recurved, stigmatic branches. Saffron grows wild in Southern Europe and the East. It is supposed to be a native of the Levant, but has been so long in cultivation that its exact geographical origin is in doubt. It is cultivated in several warm countries, especially in Spain, France, and Austria. Large quantities are also raised in different parts of Asia for home consumption. Saffron of excellent quality is produced in Pennsylvania, but scarcely on a commercial scale.

FIG. 3350.—Ovary of the Saffron Plant, Entire and in Transverse Section. (Baillon.)

Commercial saffron consists only of the stigmas, or these with as little of the upper end of the style as is practicable to get. It is collected by plucking the flowers as they open and carefully picking out these organs, which are then carefully dried with gentle heat. Seven or eight thousand flowers are said to be required for a hundred grammes of saffron. French saffron is said to be the best. Spanish is the most common.

DESCRIPTION.—The stigmas are now usually dried loosely tangled together, in a way that has given it the designation "hay saffron;" with a little shaking the individual styles can be shaken out without breaking. It is dry-feeling, but not brittle, and moderately hygroscopic. The officinal definition is as follows: Stigmas, separate, or three, attached to the top of the style, about

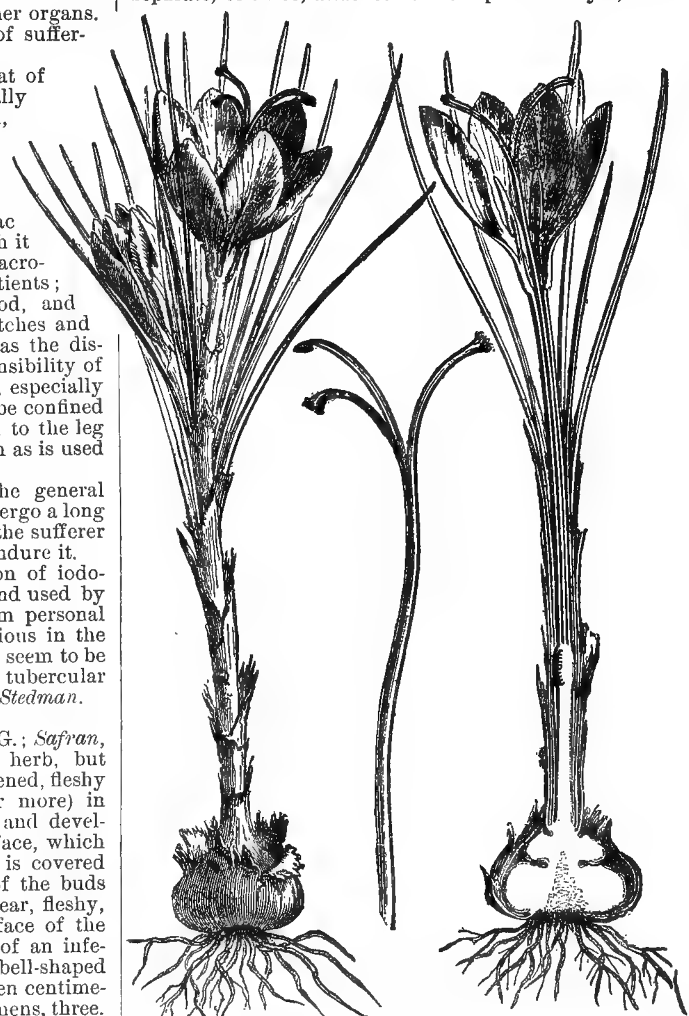

FIG. 3357.—Saffron Plant (one-half natural size); also Longitudinal Section of the same, and Style. (Baillon.)

an inch and a quarter (three centimetres) long, flattish-tubular, almost thread-like, broader and notched above: orange-brown; odor strong, peculiar, aromatic; taste bitterish and aromatic. When chewed it tinges the saliva deep orange-yellow.

The high price of this product has been the cause of many devices, nearly all of them very stupid and easily detected, to cheapen it; too much of the styles, which are worthless, may be gathered along with it; it may be mixed with stamens; the flowers of *Calendula* or other yellow *Compositæ* may be mixed in, or even substituted for it; or it may be weighted with water or oil, or colored chalk, or it may be partially exhausted. Soaking in warm water, examining with a lens, or pressing between sheets of blotting-paper will serve to detect these sophistications. The cheap drug, commonly called in domestic

parlance "saffron" in this country, is safflower, *Carthamus tinctorius* Linn., order, *Compositæ*. It is a favorite sudorific in measles, and popularly believed to favor the appearance of the eruption.

The history of saffron has a good deal of interest, since it was for centuries one of the most highly prized of drugs, a valuable dye, and a pleasant condiment or perfume. It has been known since the time of Solomon in the East, and almost as long in Asia Minor, Greece, and Italy. Its cultivation in Spain dates back seven or eight hundred years; in other parts of Europe from five to seven hundred. Its adulteration, almost as old as even its production, has always been a subject for governmental solicitude, and was punished by severe, in some countries cruel and barbarous, penalties. People have been buried alive and burnt for this crime. The uses of saffron also were much more varied, and deemed far more important, than we can imagine them now.

Composition.—Saffron contains about one per cent. of *volatile oil*, heavier than water and not very permanent, to which its odor is due. This oil appears to be variable both in quantity and properties, and is perhaps partly produced by decomposition of the crocin; Quadrat obtained an oil lighter than water; distilled with a solution of salt and potash, more than nine per cent. may be obtained (Husemann). It also contains a small amount of *gum*, fat, and *wax*. The important constituent, however, is its coloring matter, *Crocin* (polychroit), of which there is, according to Hager, sixty-five per cent. It is a deliquescent, orange-red, amorphous substance, having no odor, but a sweetish taste. Over sulphuric acid it can be dried to a bright red powder. Water and diluted alcohol dissolve it freely, absolute alcohol but little, ether not at all. By treatment with diluted acid it decomposes, and glucose and another coloring substance, *Crocitin* (crocin), are produced; this is a red powder, easily soluble in alcohol, but not in water or ether.

Action and Use.—This is the shortest paragraph in the article; as a medicine it probably has little or no value. In large doses, five to fifteen grammes (ʒ j. ad iv.), it is said to be abortifacient, in smaller ones emmenagogue and narcotic; but these properties are very uncertain, to say the least. In small doses it is moderately carminative, but no better than fifty different mints and umbellifers of about one-hundredth its cost. As a coloring agent it is superb, and has only recently been superseded by the marvellous development of the aniline series of dyes. It is still used, especially in Europe, to give color and flavor to a number of preparations. The tincture (*Tinctura Croci*, U. S. Ph.), strength $\frac{1}{10}$, is officinal.

Allied Plants.—Several other species of *Crocus* have strongly colored stigmas, and have been similarly used. *Gladiolus* and *Iris*, in the same order, are familiar names to the florist; the latter genus furnishes two or three medicines. See Orris and Flag, Blue.

Allied Drugs.—Crocin has been obtained from one or two other plants of no botanical connection with crocus. Carthamus, above-mentioned, resembles saffron slightly in color. Annato is another yellow-coloring substance, occasionally used in pharmacy, more frequently in the dairy. Red rose and cochineal give their superb colors to a few mixtures.

W. P. Bolles.

SAGE (*Salvia*, U. S. Ph.), *Salvia officinalis* Linn.; Order, *Labiatæ*. This is the well-known Garden Sage, a half-shrubby perennial, whose stems die down to within a foot or so of the ground in the fall, but branch very freely and send up numerous herbaceous, squarish, leafy, and flowering branches during the summer, twice or three times as long. Leaves numerous, those near the ground short-petioled, the upper ones nearly or quite sessile, thick, rugose, bluntly oval or oblanceolate, finely serrate. They are slightly pubescent above, often very woolly and white beneath. Flowers in a mixed spike, with two-lipped, pubescent, bell-shaped calyx, and a conspicuously labiate, blue corolla, with a ring of hairs at the base, inside. Upper lip of the corolla concave, notched at the apex, the lower three-lobed; the central one much the largest and longest. Perfect stamens two, with widely divergent anther-cells, but one of which in each stamen is perfect. Ovary four-lobed. Fruit of four achenes. Sage, like so many others of our household mints, is a native of Southern Europe. It has, however, been cultivated for centuries, and transplanted to all temperate countries. There are a few garden varieties. The flowers may be pale-blue, pink, or white, the leaves narrow, variegated, or curled.

Fig. 3358. — Salvia Officinalis, Sage; flowering branch. (Baillon.)

The leaves, or leaves and tops, are used. Dried Sage leaves have a grayish-green color, pubescent surface, and the peculiarities of shape and surface given above; they are one or two inches long, have large oil-glands upon their surfaces, and are very aromatic; taste bitter and slightly astringent.

Sage owes its very characteristic odor to less than one per cent. of a limpid greenish *essential oil*, a composite substance containing a hydrocarbon, one or more oxygenated oils, and a camphor—in short, resembling the oils of mint, patchouly, thyme, etc. It also contains a moderate amount of *tannic acid*, some *resin*, *gum*, *bitter extractive*, and common plant components.

Fig. 3359. — Flower of the Sage Plant. (Baillon.)

Their taste and odor divide the mints from each other more than chemical or therapeutic properties. Sage resembles the rest of the order in its general action; it is aromatic, a gastric stimulant, and by reason of its bitterness also tonic. It is also, what all are not, mildly astringent. In large quantities of hot water, like many other mints, it is given as a sudorific in the beginning of feverish colds, etc. Sage is useful in mouth-washes. It is, however, almost entirely a domestic remedy, and even as such but little used of late, although formerly in high repute. It is one of the ingredients of the aromatic wine (*Vinum Aromaticum*, U. S. Ph.), an old-fashioned liniment.

Allied Plants, etc.—See Peppermint.

W. P. Bolles.

SAGO (*Sagou*, Codex Med.). A starch prepared from the stems of several species of *Palmæ* growing in the Indian Archipelago, especially from *Metroxylon* (*Sagus*) *Rumphii* Mart., *M. læve* Mart., *Sagus farinifera* Lam., etc. The soft pithy stems of these palms, just before blossoming, are loaded with starch to such an extent that upon splitting them open it can be scooped out in a coarse, moist powder. This is then washed over sieves, and the cellular tissue thus separated. For European use the starch, which has passed through these strainers, is washed sufficiently, and then, while moist and thick, rubbed through a sieve. By this means it is formed into grains of the size of the meshes, which are dried in a hot pan,

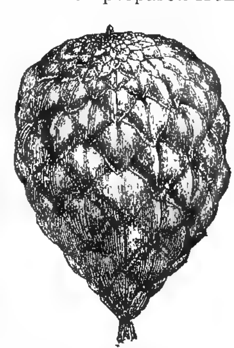

Fig. 3360.—Fruit of Sago Palm. (Baillon.)

and finally polished by friction in bags or rollers. Sago varies in appearance according to the details of this process. That most common in groceries in the United States is "Pearl Sago," in small round granules, about as large as white mustard seeds (1 mm. in diameter), white and opaque, or somewhat translucent, in places. Sago starch is in oblong, sometimes tuberculated, and angular granules, with a very excentric hilum, and frequently with separated protuberances, leaving sharply marked facets.

Sago is simply starch, and no more a medicine than arrowroot or tapioca See STARCH. *W. P. Bolles.*

SAINT-AMAND is a small city in the Département du Nord, France, in which are several mineral springs of some reputation. The place is frequented, however, chiefly by reason of the mud baths which are there given. The following is the composition of the mud:

	Grammes.
Water	55.000
Calcium carbonate	1.569
Magnesium carbonate	0.568
Iron	1.450
Sulphur	0.210
Silica	30.400
Organic matters	8.103
Loss	2.700
Total	100.000

The waters of the springs, which are used for drinking, contain sulphates of calcium, sodium, and magnesium, carbonates of calcium and magnesium, chlorides of sodium and magnesium, and silicic acid. No use is made of the water for bathing purposes. Saint-Amand is recommended chiefly for the relief of chronic and subacute rheumatic affections, of certain forms of neuralgia, and of lameness and disability following sprains or remaining as sequelæ of fractures and dislocations. A course of treatment here is also said to be of benefit in chronic congestive affections of the abdominal and pelvic organs. *T. L. S.*

SAINT-HONORE is a thermal station in the French Pyrénées, lying at an elevation of about 900 feet above sea-level. The waters of the several springs are slightly sulphuretted, and contain a large proportion of sodium chloride as compared with the other mineral constituents. The temperature of the different springs varies from 80° to 86° F.

A course of treatment at Saint-Honoré is recommended by writers to those suffering from catarrhal affections of any of the mucous membranes, incipient pulmonary phthisis, functional disorders of menstruation, and certain forms of eczema, lichen, pityriasis, and acne. In rheumatic affections baths are sometimes given, with the water heated above its natural temperature. *T. L. S.*

SAINT IGNATIUS' BEAN (*Ignatia*, U. S. Ph.). The seed of *Strychnos Ignatii* Berg, Order *Loganiaceæ*. This is a large, half-climbing shrub, with very long, slender branches, and rather large, oval, pointed, three-nerved leaves. The flowers resemble those of *S. Nux Vomica*, and the fruit is a very large (ten to twenty centimetres), solid, many-seeded, hard berry. Very little is known in detail concerning this plant. Bentley and Trimen, in their "Medicinal Botany," have been obliged to copy descriptions and figures from fifty to nearly two hundred years old, and there do not appear to be any accessible botanical specimens. It is even doubted by some whether it comes from a Strychnos at all, but the peculiar structure and composition of the seeds make this almost certain on indirect evidence. The plant grows in the Philippine Islands, and has been introduced into Cochin-China. The fruit appears to be not uncommon in some Asiatic markets. The seed has been known to Europeans since 1699 (Flückiger).

Saint Ignatius' Beans are hard, oblong but irregularly faceted seeds, two or three centimetres in length, of a dull yellowish-gray or blackish color, and corneous texture; they are normally covered with short, coarse, appressed, glistening hairs, but these are usually rubbed off before they reach this country, probably by the friction of the long voyage, or carriage. The seed consists mostly of perisperm, but contains an oblong embryo, six or eight millimetres in length, in a cavity near the centre. The seeds have but little odor, and a very bitter taste.

COMPOSITION.—*Strychnine*, to the extent of from one to one and a half per cent.; *brucine* from one-half to three-fourths per cent.; considerable albuminoid matters; no starch. These seeds, from chemical, structural, and physiological points of view, are qualitatively so exactly duplicates of Nux Vomica, that the reader is referred to that article for further information. An abstract (*Abstractum Ignatiæ*, U. S. Ph.) and a Tincture (*Tinctura Ignatiæ*, U. S. Ph.) are to be had at the pharmacies. *W. P. Bolles.*

SAINT JOHN'S BREAD (*Caroube*, Codex Med.). The fruit of *Ceratonia siliqua* Linn., order *Leguminosæ*, a medium-sized "Locust" of Southern Europe and the Levant, whose English name is derived from the tradition that it formed part of the food of The Baptist while in the desert. It consists of pods of an oblong-linear, curved outline, ten or fifteen centimetres (four to six inches) long, two or three broad, and about one (or less) thick. They have a dull-glossy brown surface, and a sweetish, dry-pulpy texture. The pea-like, but slightly albuminous seeds, are imbedded in this pulp.

St. John's bread has no medicinal value whatever. It forms a poor article of food in Spain, Italy, etc., and is also fed to cattle. In this country it is scarcely to be met with, excepting at a few shops in the larger cities, where it is kept to supply a slight demand of Spanish and Italian immigrants.

ALLIED PLANTS, ETC.—See SENNA, CASSIA FISTULA, etc. *W. P. Bolles.*

SAINT JOHN'S WORT (*Millepertuis*, Codex Med.). *Hypericum perforatum* Linn., order *Hypericaceæ*. A troublesome weed, with a much-branched, herbaceous stem, somewhat flattened, from thirty to sixty centimetres high, elliptical-oblong, dotted leaves, acrid juice, and numerous rather showy, regular, yellow flowers. Sepals five, lanceolate-pointed. Petals five, large, rounded. Stamens numerous, in five bundles. Styles three, pod three-celled.

This and other Hypericums have had in time past considerable reputation in diarrhœa, rheumatism, insanity, etc., as well as in the form of liniments as vulneraries. All are at present obsolete, excepting in domestic use. *W. P. Bolles.*

SAINT LOUIS. The accompanying chart, representing the climate of the city of St. Louis, Mo., and obtained from the Chief Signal Office at Washington, is here introduced for convenience of reference. A detailed explanation of this chart, and of other like charts published in the HANDBOOK, is given in the general article on Climate, where also the reader will find suggestions as to the best method of using these charts.

St. Louis has one of the most extreme climates to be found within the limits of the United States. In illustration of this fact the reader is referred to the data of column J. By comparing the St. Louis and New York City charts we learn that although the mean temperature in winter at St. Louis is only two and a half degrees higher than that of New York, the mean summer temperature of the former is five and one-third degrees higher than that of the latter. The daily range of temperature is decidedly greater at St. Louis than at New York; yet, despite this fact, the day and night figures are in summer both of them so high that cooler nights are to be found at New York with a relatively low nycthemeral range of temperature. Column K shows us that month by month throughout the year the St. Louis climate is drier than the climate of New York. Columns L, M, and N show that the former is less cloudy, especially in summer and autumn, than is the latter. The prevalence of south winds throughout the year is a notable feature of the St. Louis climate; the blizzards of

SAINT MORITZ. The climate of Saint Moritz, considered as a winter health-station, has already been sufficiently described in the article entitled Engadine. In the present article a few words will be said concerning the summer climate of this celebrated resort of the High Alps, and concerning its valuable mineral springs. The wood-cuts on page 246 (Figs. 3361 and 3362), copied from Woldemar Kaden's "Baths of St. Moritz," are presented to the reader as illustrations of the descriptive passages in the Engadine article, where they would have been more properly introduced had they been available to the writer when that article was prepared for press. These illustrations will be especially interesting to a reader of Dr. Yeo's work on "Climate and Health-resorts," and if studied in connection with the lengthy and interesting descriptions of scenery therein given, will convey to the mind a very accurate impression of the topography and scenery of the Upper Engadine.

In studying the illustrations it should be borne in mind that the direction of the Upper Engadine valley is from southwest to northeast.

The view in Fig. 3361 is taken from an elevated point on the eastern side of the valley, just south of the St. Moritz bathing establishment, and shows the valley as seen on looking north from this point. In the foreground are seen the Kurhaus, bathing establishments, and hotels constituting St. Moritz Bad, or the Baths of St. Moritz. Near the centre of the picture is seen the village of St. Moritz, built upon the northern slope of the valley, at an elevation of some two to three hundred feet above the lake of the same name. The mountains which close in the view to the north are a portion of the range of the Albula and Bündner Alps, the lofty serrated peak seen directly in line with the village of St. Moritz and towering above all other summits visible in the picture being the Piz Kesch (11,211 feet high above sea-level; 5,411 feet above St. Moritz Lake).

In Fig. 3362 the view is taken from an elevated point on the western side of the valley, just north of the village of Campfer; probably from the "summer restaurant known as the Alpina," mentioned by Dr. Yeo (*op. cit.*, p. 192). In this view we are looking up the valley, instead of down the valley as in Fig. 3361. The baths of St. Moritz are behind us on the left: and not very far distant either; for Dr. Yeo, in describing Campfer, tells us that "it is a convenient abode for those visitors to the Baths of St. Moritz who would be at St. Moritz, but not of St. Moritz," being "as near the Kurhaus and the baths as the village of St. Moritz itself." It is the village of Campfer that is seen in the immediate foreground of this picture. The little village standing in the distance is that of Silva Plana. The lake in the foreground is that of Campfer, the one in the background beyond Silva Plana is the lake of Silva Plana. The lake of Sils, the village of Sils, and the Maloja we do not see; they are hidden behind the mountain-shoulder which rises behind Silva Plana; but the great snow-covered alp which closes in the view to the southwest is the Piz Margna, one of the three Bernina mountains whose slopes are said by Dr. A. T. Tucker Wise to abut on the lake of Sils and on the eastern side of the Maloja plateau ("The Alpine Winter Cure," p. 66). The elevation of the Piz Margna above sea-level is 10,355 feet. A reader of Dr. Yeo's book will easily recognize another prominent object in this picture, namely, the location of "the restaurant and summer house called *Crest-alta*, which is finely situated on the top of a wooded promontory which projects in the most picturesque manner from the south side of the valley into the Campfer lake." This promontory is seen just to the left of the centre in our illustration.

SUMMER CLIMATE.—The following tables, taken from Woldemar Kaden's interesting pamphlet, will serve

Fig. 3361.—Baths and Village of St. Moritz. (From "The Baths of St. Moritz," by Woldemar Kaden.)

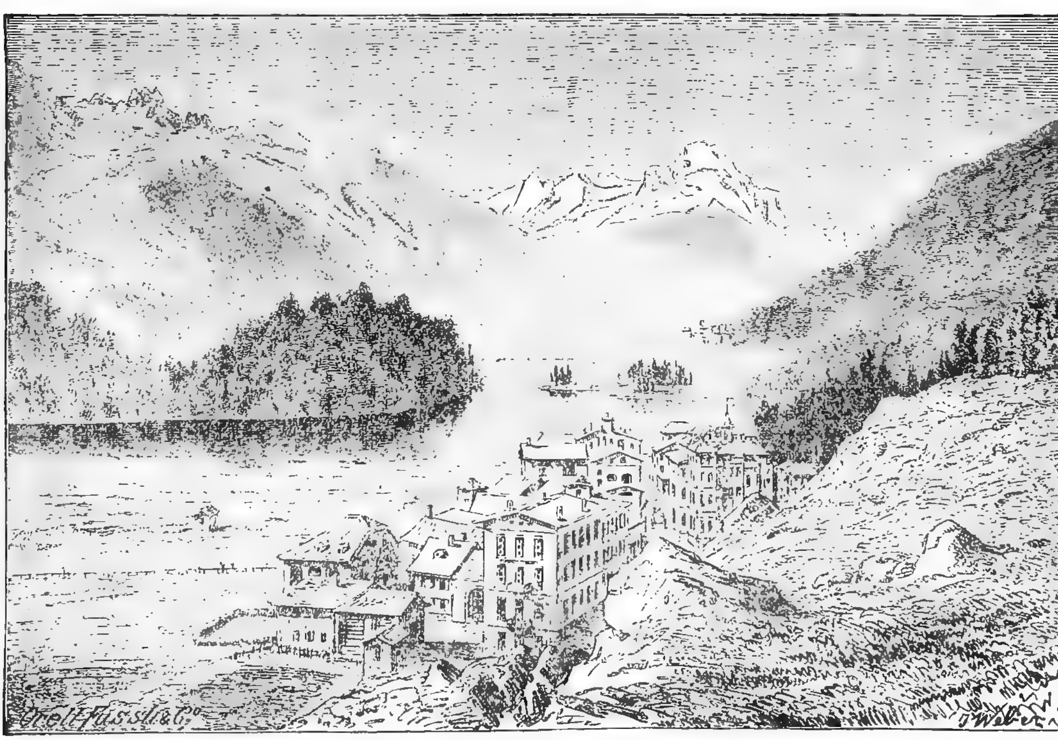

Fig. 3362.—Campfer, near the Baths of St. Moritz and Piz La Margna. (From "The Baths of St. Moritz," by Woldemar Kaden.)

sufficiently to illustrate the summer climate of Saint Moritz:

Mr. Kaden states that July and August are the best months for a summer stay at Saint Moritz, and that April and May, being the snow-melting months, are the very worst season of the year in the Engadine.

MINERAL WATERS.—There are two chief mineral springs at the baths of Saint Moritz, known respectively as the "Alte-Quelle" and the "Paracelsus-Quelle;" of these the latter appears to be a trifle the richer in mineral ingredients, but the two are very similar one to the other. A very full analysis of the two waters may be found on pages 58 and 59 of Mr. Kaden's pamphlet. Dr. Yeo (*op. cit.*, p. 160) also gives an analysis of the Saint Moritz waters. He sums up the characteristics of the waters as follows: "Practically these waters may be regarded as containing a small quantity of iron, about three grains of the carbonate in a gallon of the stronger source, and a considerable amount of carbonate of lime, about eighty grains in a gallon, held in solution by an abundance of carbonic acid. The presence of this large amount of carbonate of lime in the absence of any appreciable amount of aperient saline constituents, interferes somewhat with the usefulness of this water in many cases where the use of a chalybeate is indicated." The duration of the course of treatment by baths, etc., usually recommended, is from three to eight weeks. For full information concerning the proper use of the waters and the class of maladies ameliorable by such proper use, as well as the type of disease and of constitution indicating the propriety of recourse to this "high altitude" bathing-station, and the class of invalids and type of constitution which should be forbidden to resort thither, see Dr. Yeo's book and Mr. Kaden's pamphlet, in both of which works (the former especially) these matters are treated ably and at very considerable length. For general indications see articles "Health-resorts" and "Mountain Resorts."

Huntington Richards.

SAINT-OLAFSBAD is a health-resort in Sweden, not far from the city of Christiania, which is visited to some extent by foreigners on account of its iron-spring. This water contains 0.114 Gr. of mineral constituents, about fifty per cent. of which is ferrous carbonate, in each litre. There are various other "cures" made use of, such as pine-needle baths, mountain climbing, frictions with peat, milk and whey cures, etc.

The affections for the relief of which Saint-Olafsbad is visited are anæmia, chronic bronchitis, chronic rheumatism, debility attending tedious convalescence from acute diseases, etc. The place is well protected against the north winds, and the climate is more mild than in other places in the vicinity. The season for guests lasts from about the end of May to the first of September.

T. L. S.

SAINT PAUL. The accompanying chart, representing the climate of the city of Saint Paul, Minn., and obtained from the Chief Signal Office at Washington, is here introduced for convenience of reference. A detailed explanation of this chart, and of other like charts published in the HANDBOOK, may be found in the general article on Climate; where also suggestions are made as to the best method of using these charts. St. Paul and other points in Minnesota were greatly in vogue a few years ago as winter resorts for persons in the early stage of pulmonary phthisis, and very many such persons have no doubt been benefited by residence in the steady cold of the Minnesota winter; but, since the somewhat over-rapid growth of its chief towns has set in, and since the discovery of other and better climates of the bracing winter type, the reputation of Minnesota as a health-resort has considerably declined.

A comparison of columns L, M, and N of the St. Paul chart with corresponding columns of the New York City chart, demonstrates the fact that during the winter and summer seasons a less degree of cloudiness prevails at the former than at the latter station. During the spring season, on the contrary, New York City appears to be slightly less cloudy than St. Paul. The spring, fall, and winter rainfall at St. Paul is greatly less than at New York. In the matter of windiness the climates of the two places are very much alike in spring, summer, and autumn; but in winter the slight difference (in favor of St. Paul) existing between the two becomes very considerable, New York City, according to the figures of column S, being nearly twenty-three and two-thirds per cent. more windy at that season than is St. Paul. In the matter of relative humidity the climates of the two places are in winter almost precisely alike, such trifling difference as exists being in favor of New York City; in summer and autumn scarcely any difference between the two exists. In spring, however, and notably in the two months of March and April, the relative humidity at St. Paul is markedly less than at New York City. The absolute humidity of St. Paul, during the winter season in particular, is less than that of New York City, being at that season only half as great. In summer the two places differ little in absolute humidity of atmosphere. The actual figures for the two places are as follows, assuming for convenience of calculation that the mean summer temperature of New York is 0.5°, and that of St. Paul 0.6° higher than the actual figures, and that in winter New York City's mean temperature is 0.6°, and St. Paul's 0.4° higher than shown by the figures of Column AA.

	Mean summer temp.	Mean summer abs. humidity.	Mean winter abs. humidity.	Mean winter temp.
New York City	72°	5.973	1.537	32°
St. Paul	70°	5.586	0.823	17°

It is in the matter of temperature that we find the chief difference between the climates of the two places. The mean temperature of November at St. Paul is the same as that of January at New York City; while the mean temperature of the four months, December, January, February, and March is at New York 32.8° F., at St. Paul only 19.6° F.

Steady cold in winter, involving exemption from thaws, is the chief cause of the popularity formerly enjoyed by Minnesota as a resort for phthisical patients, and is the leading factor in its climate (combined with relative windlessness and cloudlessness, and its inland location, involving freedom from the perpetual changes from land to sea air, and from sea air to land air, common along the Atlantic coast), which renders the truly and purely continental climate of that State more favorable to weak lungs than is the climate of any of the larger seaboard cities of the Northern United States. *H. R.*

SAINT-SAUVEUR is a little hamlet in the Département des Hautes-Pyrénées, France, lying at an elevation of 2,500 feet above the sea. The valley in which the village lies is exposed to the north and south winds, but the climate is nevertheless equable and mild. There are two principal springs—the Source des Bains or des Dames, and the Source de Hontalade. The following is the composition of the waters, after analyses made by Filhol and Byasson. In 1,000 parts of water there are of

	Source des Bains.	Source de Hontalade.

Total	0.2500	0.2884

There are traces of iodine and boracic acid. The waters issue at a temperature of 94° and 71° F., respectively.

The indications for a course of treatment at Saint-Sauveur are stated to be catarrh of the bladder, gravel, gastralgia, chronic diarrhœa, menstrual disturbances, certain uterine affections, pulmonary phthisis, and irritable conditions of the nervous system. The therapeutic means employed are baths, both general and local, douches, and the internal use of the water. The season extends from about the first of June to the middle of September. A single course of treatment generally occupies about four weeks. *T. L. S.*

SALEP, Codex Med. (*Tubera Salep,* Ph. G.). The corms of several European and Asiatic *Orchidaceous* plants, especially of *Orchis mascula* Linn., *O. Moris* Linn., *O. militaris* Linn., *O. variegata* Linn., etc., dried by means of artificial heat. It is in the form of small round, oval, or irregular tubers of a yellowish color and rather translucent texture. Salep is tough and hard to pulverize; it has a mucilaginous taste and very little odor; consists of a small quantity of starch and a good deal of bassorin-like gum, with no more active ingredients, and is simply a not very nutritious food, devoid of physiological or therapeutic value.

ALLIED PLANTS.—See VANILLA.
ALLIED DRUGS.—See TRAGACANTH; STARCH.

W. P. Bolles.

SALICYLIC ACID AND SALICYLATES. Salicylic acid, chemically *ortho-oxybenzoic acid,* $HC_7H_5O_3$, takes its name from the principle *salicin,* found in willow-bark, from which substance it is possible to make salicylic

acid by fusion with potassic hydrate. Salicylic acid in the condition of the ethereal salt, *methyl salicylate*, constitutes about ninety per cent. of oil of gaultheria (wintergreen), and occurs also in other plants. Salicylic acid can be made from oil of gaultheria, but at present almost all the acid used in medicine is made by the process of Kolbe, from carbolic acid. The principle of this process consists in the forcing upon the molecule of carbolic acid a molecule of carbon dioxide, an addition which just converts one molecule of the phenol into one of salicylic acid. By the process, carbolic acid and a concentrated solution of soda are first evaporated to dryness, and over the product, heated, a stream of dry carbon dioxide is made to pass. As a result, one half of the phenol used is converted into salicylic acid in condition of sodic salicylate, which salt, on decomposition by treatment of its aqueous solution with hydrochloric acid, yields salicylic acid under its own form. Kolbe's process, by reason of its cheapness, has practically superseded all others for the procurement of salicylic acid. Salicylic acid is officinal in the U. S. Pharmacopœia under the title *Acidum Salicylicum*, Salicylic Acid. It presents itself as "fine, white, light, prismatic, needle-shaped crystals, permanent in the air, free from odor of carbolic acid, but sometimes having a slight aromatic odor, of a sweetish and slightly acrid taste, and an acid reaction. Soluble in 450 parts of water, and in 2.5 parts of alcohol at 15° C. (59° F.); in 14 parts of boiling water; very soluble in boiling alcohol; also soluble in 2 parts of ether, in 2 parts of absolute alcohol, in 3.5 parts of amylic alcohol, and in 80 parts of chloroform. When heated to about 175° C. (347° F.) the crystals melt, and at about 200° C. (392° F.) they begin to sublime; at a higher temperature they are volatilized and decomposed with odor of carbolic acid. The aqueous solution is colored intensely violet-red by test-solution of ferric chloride" [one part of ferric chloride dissolved in ten parts of distilled water] (*U. S. Ph.*). Although salicylic acid is but feebly soluble in cold water, it dissolves freely in many saline solutions. Thus the pharmacopœial *solution of acetate of ammonia* will dissolve twenty-five per cent. of salicylic acid; a twelve and a half per cent. aqueous solution of potassic acetate will dissolve twelve and a half per cent. of the acid; a twelve and a half per cent. solution of potassic citrate in equal volumes of glycerin and water will dissolve six per cent. All of these solutions possess the sharp stinging taste of the uncombined acid. A serviceable and permanent solution of the acid, and one that instead of being sharp to the taste has a pure bitter flavor only, can be made as follows: Dissolve two parts of borax in twelve of glycerin by the aid of heat; add one part of salicylic acid, continue the heat, and stir until the acid dissolves. Almost all solutions of salicylic acid, either immediately or after a while, turn of a reddish or of a smoky color resembling that of solutions of carbolic acid.

Salicylic acid, taken into the mouth, has not much taste, proper, but speedily and quite suddenly after the tasting a sharp stinging seizes the *throat*, often severe enough to bring tears to the eyes. Similarly, a little of the dry acid snuffed up the nostrils will sting quite strongly. The acid brings sharp pain to cuts and abrasions, but, swallowed, is much less irritant to the stomach than its effects on the throat would lead to suppose. Large doses, so taken, may upset digestion and cause a strong sensation of heat, and even actual burning pain, but no serious or lasting results follow. The acid is rapidly absorbed from the stomach into the circulation, presumably in saline combination, and thereupon exerts the peculiar influence characteristic of the salicylates (see *Salicylates*, below).

Salicylic acid was at first used as an internal medicine for the procurement of the therapeutic effects of the salicylates; but now, and very properly, salicylates themselves, because of their freedom from the locally irritant action of the uncombined acid, have superseded the acid for this purpose. The present medicinal application of the acid is for local purposes as a deodorant, detergent, or so-called antiseptic—purposes which salicylic acid fulfils by reason of its possession of a fairly potent germ-sterilizing faculty. (See Salicylic Acid in article Germicides.) For general local use, the solution of the acid in a glycerin solution of borax is convenient, this solution bearing any necessary dilution with either water or alcohol without precipitation. A dilution representing a two per cent. solution of acid is one very commonly employed. For other salicylic preparations for local use, see Salicylic Acid in article Antiseptics.

Salicylates.—In saline combination, whether with metallic or ethereal bases, the local pungency of free salicylic acid disappears while yet the faculty for constitutional action remains. As already said, it is probable that the acid, when taken as an internal medicine, enters the circulation only after conversion into a salicylate, so that, as a matter of fact, what is commonly called the constitutional action of salicylic acid is, so far as we know, the action of a salicylate. The constitutional effects in question are as follows: After a full dose a non-pyrexial subject experiences, in about fifteen minutes, a moderate reddening of the face with a sense of fulness of the head, or perhaps even a pronounced headache, and with a buzzing or roaring in the ears precisely similar to what occurs in cinchonism. Almost simultaneously free perspiration begins, and, according to dose, there is more or less tendency to a reduction of pulse-rate, of respiration-rate, and of body-temperature. Tests for salicylic acid will reveal the presence of the substance in the urine, the saliva, and the sweat. The urine will furthermore be discolored, appearing brown by reflected, and green by transmitted, light. It will also contain a something that will reduce copper salts in copper test-solutions (Brunton). In overdoses, salicylates readily irritate the kidneys, setting up albuminuria; may derange the cerebral faculties, causing hallucinations and delirium; and may dangerously or even fatally depress the functions of heart and lungs, determining collapse or death by failure of respiration. These several untoward effects vary a great deal in readiness of occurrence, and, according to Squibb, in "a very large proportion" of instances are determined, not by the salicylic acid, but by a *contaminating acid* very commonly present in market samples of salicylic acid, and hence in salicylates derived therefrom. The medicinally valuable constitutional effects of salicylates do not appear in experimentation with a subject in health. They consist, in general, in a reduction of fever-temperatures, and, in particular, in an abatement of pains in fibrous tissues, notably the pain of affected parts in acute articular rheumatism; and in an occasionally seen abatement of the glycosuria in saccharine diabetes. The antipyretic power of salicylates is second to none, in all the three elements of quickness, degree, and duration of reduction of temperature. For a full antipyretic effect, however, considerable dosage is necessary—considerable enough to cause disagreeable sweating, *tinnitus aurium*, depression of pulse and respiration-rate, and, every now and then, actual toxic symptoms. The antirheumatic faculty of salicylates is unapproached by any other known medicine, so that, as is well known, salicylates constitute a standard set of medicines for the treatment of acute rheumatism. Various opinions have been held concerning the efficacy of salicylates to accomplish more in this disease than the obvious reduction of temperature and abatement of pain. Some maintain that these effects are all that can properly be ascribed to the medicine; while others consider statistics to show for salicylate treatment a shortening of the duration of the rheumatic attack and a lessening of the frequency of cardiac complications. The antidiabetic power of salicylates, as is the case with the same faculty shown by other medicines, is very variably manifest in different cases of glycosuria. Sometimes the effect is *nil*, while in other cases the sugar may, for a while at least, totally disappear from the urine as the direct result of salicylate treatment—the diet remaining as before during the period of the observation. For decided results full dosage is necessary, and full doses are often exceedingly well borne in diabetes, the subject hardly experiencing any obvious derangement from the medicine.

The salicylates in *common medical use* for the purpose of salicylate medication are the salicylates, respectively, of *sodium, lithium,* and *methyl*—the last named in the shape of the volatile *oil of gaultheria,* which consists of ninety per cent. of methyl salicylate. The salicylates, respectively, of *physostigmine, quinine,* and other alkaloids, are used for the sake of the medicinal action of the respective bases only.

Sodic Salicylate, $2NaC_7H_5O_3.H_2O$. The salt is official in the United States Pharmacopœia under the title *Sodii Salicylas,* Salicylate of Sodium. It is thus described: "Small, white, crystalline plates, or a crystalline powder, permanent in the air, odorless, having a sweetish, saline, and mildly alkaline taste, and a feebly acid reaction. Soluble in 1.5 parts of water, and in 6 parts of alcohol at 15° C. (59° F.); very soluble in boiling water and in boiling alcohol. When heated, the salt gives off inflammable vapors, and leaves an alkaline residue amounting to between thirty and thirty-one per cent. of the original weight, which effervesces with acids, and imparts to a non-luminous flame an intense yellow color, not appearing more than transiently red when observed through a blue glass. On supersaturating the aqueous solution with sulphuric acid, a bulky, white precipitate is obtained, which is soluble in boiling water, from which it crystallizes on cooling; also soluble in ether, and striking an intense violet color with ferric salts" (*U. S. Ph.*). Sodic salicylate is the most commonly used salicylate, and is a very important medicine. It is easily made *in solution* by mixing salicylic acid and a sodic carbonate in the presence of water, whereupon sodic salicylate results, and remains in solution, and carbon dioxide gas escapes in effervescence. From this solution the salt can be obtained by evaporation to dryness, carefully conducted. Extemporaneous preparation of the medicine *in solution* being easy, Squibb points out an advantage of such extemporaneous making of the salt in all cases where the prescriber or the dispenser may not be certain of the purity of the market article. The point is that the purity of a given sample of *sodic salicylate* is not easy of establishment except by an elaborate chemical analysis, whereas a good sample of *salicylic acid* is immediately recognizable by the simple fact of its *crystalline condition.* Hence, in making one's own sodic salicylate from a selected well-crystallized sample of salicylic acid, purity is assured. And in the instance of this salt purity is important, since, as above said, there is probably good reason to lay many of the untoward effects of salicylates to the door of the contaminating acid of salicylic acid. Squibb recommends the following formula for the preparation of a solution of sodic salicylate of a strength convenient for use as a medicine: "Take of salicylic acid, well crystallized, 437 grains = 28.32 grammes; bicarbonate of sodium, 270 grains = 17.5 grammes; water, free from iron, a sufficient quantity. Put the acid into a vessel of the capacity of a pint, add 4 fluidounces = 120 c.c. of water, stir well together, and then add the bicarbonate of sodium in portions with stirring, until the whole is added and the effervescence is finished. Filter the solution, and wash the filter through with water until the filtered solution measures 6 fluidounces, or 180 c.c. This solution contains 10 grains (= 0.65 grammes) of the medicinal salicylate of sodium in each fluidrachm (= 3.75 c.c.). If made from good materials, the solution before filtration is of a pale, amber color, but as most ordinary filtering paper contains traces of iron, the filtered solution is often of a deeper tint." The proportions of the ingredients for this solution are estimated so that the solution shall be neutral, but, "owing to the varying proportions of hygrometric moisture in the materials," the neutrality may not always be absolute. According to Squibb, a well-made sample of sodic salicylate, prepared by use of a well-crystallized sample of acid, is always, when evaporated to dryness, *white,* and is free from all *odor of carbolic acid,* unless it have been shut up for a long while in a bottle. Even then, however, the odor should be but very faint—only perceptible on close examination, and should disappear upon exposure of the sample to air. *Solutions* of sodic salicylate of good quality should have none of the carbolic acid smell.

Sodic salicylate is used almost exclusively as an internal medicine, being commonly held to be lacking in the germ-sterilizing faculty which gives salicylic acid, as such, its applicability as a local antiseptic. For the purposes of internal salicylate-medication, as set forth above, the salt is thoroughly effective, and, if made from a well crystallized and therefore fairly pure sample of salicylic acid, rarely produces untoward effects in reasonable doses. So large a quantity as 5.00 Gm. (about seventy-seven grains) has been given at a single dose in rheumatism without producing serious derangement, but the ordinary dosage for an antipyretic or antirheumatic effect does not exceed 1.30 Gm. (twenty grains) repeated every two hours, for three or four doses, or until a distinct impression is produced, followed by doses of half the quantity every hour or two thereafter, as long as the influence of the medicine may be required. In diabetes, doses of 1.30 Gm. (twenty grains) three or four times daily may be required, and can often be borne without derangement of the stomach or an unpleasant degree of ringing in the ears. The medicine is readily enough taken in simple aqueous solution, but if the faint, mawkish taste of the salt be objected to, the addition of twenty per cent. of glycerin and the flavoring with a drop or two of oil of gaultheria will render the mixture perfectly palatable.

Lithic Salicylate, $2LiC_7H_5O_3.H_2O$. The salt is official in the United States Pharmacopœia under the title *Lithii Salicylas,* Salicylate of Lithium. It is thus described: "A white powder, deliquescent on exposure to air, odorless, or nearly so, having a sweetish taste, and a faintly acid reaction. Very soluble in water and in alcohol. When strongly heated, the salt chars, emits inflammable vapors, and finally leaves a black residue having an alkaline reaction, and imparting a crimson color to a non-luminous flame. On supersaturating the dilute aqueous solution with hydrochloric acid, a bulky, white precipitate is obtained, which is soluble in boiling water, from which it crystallizes on cooling; also soluble in ether; and producing an intense violet color with ferric salts" (U. S. Ph.). The effects of this salt are similar to those of sodic salicylate, with the possible super-addition of medicinal virtues, in rheumatic or gouty cases, derived from the basic element. The dose is similar to that of the sodic salt.

Methylic Salicylate, as already said, is used only as it occurs as the main ingredient of the volatile oil of gaultheria. See Wintergreen. *Edward Curtis.*

SALIES-DE-BÉARN is situated in a well-protected valley in the Département des Basses-Pyrénées, France. There are several springs here, all strongly saline, the most important of which is the Source du Baillat. The following is the composition of this water, according to the analysis of Henry. One litre contains:

	Grammes.
Sodium chloride	216.020
Potassium chloride	2.080
Sodium sulphate, Magnesium sulphate, Calcium sulphate, Potassium sulphate	9.750
Magnesium and calcium bicarbonate, Ferrous oxide, organic matter	5.500
Silica and alumina	1.056
Total	234.406

There are traces also of iodine and bromine.

The waters are used externally and internally in the treatment of so-called scrofulous affections of the glands, bones, and articular structures, of subacute and chronic rheumatism, and of anæmia following hæmorrhage, or induced by long-continued suppuration. *T. L. S.*

SALINS is a small village in the Département du Jura, France, lying at an elevation of about a thousand feet above sea-level. The climate is subject to considerable changes of temperature, the days often being quite warm while the mornings and evenings are cool. There are

several mineral springs, the most important of which is known as the Puits à Muire (Grotto A). The following is the analysis made by Réveil. One litre contains:

	Grammes.
Sodium chloride	22.74516
Magnesium chloride	0.87013
Potassium chloride	0.25652
Potassium bromide	0.03065
Calcium sulphate	1.41667
Potassium sulphate	0.68080
Total	25.99993

There are traces also of sodium iodide and of calcium and magnesium carbonates.

When employed for bathing purposes this water is sometimes strengthened by the addition of a brine containing about 320 Gm. of saline constituents to the litre.

The waters are used internally and, in the form of baths, douches, and local compresses, externally. Like other waters of this group, they are employed chiefly in the treatment of rheumatic troubles, anæmia, and the so-called scrofulous affections. *T. L. S.*

SALIVATION. The term salivation is used to denote a superabundant secretion and flow of saliva. This use of the word has been objected to on the ground that salivation should properly signify a physiological act, in analogy, perhaps, with such words as urination, defecation, lactation, and the like. But the Latin word *salivatio* is derived from the transitive verb *salivo* (from *saliva*), which means to salivate, to produce an excessive flow of saliva. The synonym *ptyalism* would, perhaps, be less liable to ambiguous construction. The term *sialorrhœa*, while indicating an abnormal flow, does not necessarily imply abnormal secretion. It often happens that saliva accumulates in the mouth or drools from the lips, through failure in the act of deglutition, even when not produced in abnormal quantity. Thus in sleep, especially in certain conditions of debility, and when the head is in a dependent position, the saliva may escape from the mouth because the muscles or nerves of deglutition are inactive, as it does habitually from a similar cause in the case of imbeciles. Similarly, when, in consequence of inflammation of the throat, as in acute tonsillitis, the act of swallowing is instinctively avoided or rendered impossible through tumefaction of the parts, the saliva often appears to be in excess; but this is due rather to passive accumulation than to any excess of secretion from reflex irritation.

As to the exact amount of secretion necessary to constitute a superabundance, it is difficult to speak definitely. Normally, the quantity of the secretion varies from two to three pints in the twenty-four hours. In salivation it is often increased to from three to four pints, and may reach six or eight pints or more in the day. In the simplest cases it may only be sufficient to cause moderate discomfort from the frequent necessity of swallowing or spitting; in the most aggravated cases, on the other hand, salivation becomes a fatal malady, partly through the prolonged and excessive drain upon the economy by the loss of the solids contained in the salivary discharge, and partly through the intensity of the concomitant stomatitis and the interference with nutrition consequent upon the inability to swallow the necessary food.

In addition to the increase in quantity, there is also more or less alteration in the character of the secretion. The proportion of water may be either increased or diminished—the latter more particularly in inflammatory conditions, when the solid ingredients are augmented. The saliva is then cloudy in appearance, and often contains gray or blackish flocculi. In certain nervous forms of salivation albumen may be present in the secretion. The ptyaline is usually diminished in quantity. The reaction is commonly neutral or alkaline, and but rarely acid; in the latter case the acidity is said to be due to the buccal mucus. In cases accompanied with stomatitis the salivation is attended with a fetid and characteristic odor.

The association of stomatitis with salivation, while very common, is by no means necessary. Very often the buccal inflammation is the primary and more essential disease, the ptyalism being secondary to it and the result of irritation reflected from the mucous membrane of the mouth to the salivary glands. In other cases both the ptyalism and the stomatitis are more or less the direct effects of a common cause. But there is no evidence that ptyalism, as such, can be the cause of stomatitis.

A very common cause of salivation is a reflex irritation of the glands, which has its starting-point in the buccal mucous membrane. The irritation is conveyed by the centripetal nerves to the medulla, and thence transmitted through the secretory filaments of the chorda tympani to the salivary glands. This irritation may be excited by the so-called "topical" sialagogues—strong acids and alkalies, ethereal substances and the various masticatories, such as pyrethrum, horseradish, ginger, mezereon, tobacco, cubebs, and the like. Again, the irritation may proceed from the teeth, as in dentition or dental caries. Erythematous stomatitis, aphthæ, buccal ulceration, ulcero-membranous stomatitis, gangrene, and cancer of the mouth are likewise all attended with salivation in greater or less degree. In the mercurial and scorbutic forms of salivation, gingivitis or more extensive inflammation is an almost invariable accompaniment, and the latter commonly precedes the ptyalism. In many of these cases, however, when the flux first appears, the swelling and redness of the mucous membrane are concealed by thickening and opacity of the epithelium, so that the presence of the stomatitis might easily be overlooked. So far as the scorbutic form is concerned, the sialorrhœa is doubtless dependent solely upon the buccal inflammation.

Again, irritation may be transmitted to the salivary glands in a similar manner from regions more remote than the mouth. Nausea is commonly attended with abnormal flow of saliva, as are various forms of disease of the stomach, or even the presence of food, the irritation being communicated to the medulla through the vagus and thence to the salivary glands. Frerichs found that the saliva was secreted abundantly so soon as food was introduced into the stomach through a gastric fistula. It is said also that irritation of the splanchnic nerve, whether by means of an electric current or through intestinal disease,. may produce salivation. Ptyalism may be associated with the presence of intestinal worms.

The salivation that sometimes occurs as a symptom of pregnancy has been attributed directly to irritation of the uterine nerves, but not improbably it is the nausea that usually attends this condition, and the consequent irritation of the pneumogastric, which is the more direct cause of the ptyalism. According to Dewees, in all pregnant women there is more or less excess in the secretion of saliva. When the salivation is marked the salivary glands are usually swollen and tender, and there is a certain degree of swelling and congestion of the buccal mucous membrane. The gums, however, do not become sore, spongy, or ulcerated, and there is no fetor from the mouth. The amount of saliva secreted varies, but may reach as high as three or four quarts in the twenty-four hours (Tanner). The affection generally begins at an early period of gestation, coincidently with the period of the so-called "morning sickness," disappearing generally by the end of the third month; though it may persist during the entire course of pregnancy, and, in some rare instances, for one or two months after parturition. It is stated that menstrual troubles also may give rise to ptyalism.

A "nervous" form of salivation may be the result either of transitory impressions on the sensorium or of neuropathic conditions of the nerves or nerve-centres. Of the former a common example is the so-called "watering of the mouth," at the sight or suggestion of certain kinds of food. "Frothing" of the mouth, another form of sialorrhœa, may be the result of mental emotion. Mental disease (acute mania, melancholia, hypochondria) may also be accompanied with ptyalism. The same affection may occur as a symptom of facial neuralgia, or of disease of the medulla, brain, or spinal cord. It is observed in connection with certain forms of partial or general paralysis, and with progressive muscular atrophy;

also in hystero-epilepsy and in rabies. In some of these cases it is possible that a condition of atony of the submaxillary ganglion may account for the salivation. According to Claude Bernard, this ganglion has a moderating or inhibiting action upon the secretory function of the salivary glands, and when its influence is withdrawn, the secretory filaments of the chorda are free to act without restraint.

Sometimes salivation, occurring in connection with certain fevers, has the character of a "critical" flux. It has been observed in pneumonia, typhoid fever, dysentery, and other acute febrile diseases. This form, however, is rare.

It remains to speak of the ptyalism that is the result of the systemic or toxic action of certain medicaments. These, in contradistinction to the sialagogues that owe their effect solely to topical irritation of the buccal mucous membrane, are known as "general" or "remote" sialagogues. Such are jaborandi, physostigma, muscarin (obtained from bitter orange), tobacco, mercury and its compounds, the compounds of iodine, gold, and copper, and also the so-called nauseants. The last-named doubtless produce this effect upon the salivary glands reflexly, through the gastric division of the vagus. With regard to the others, the mode of action has been too little studied to justify positive conclusions. It is quite possible that in some instances the effect is due to a toxic irritation of the medulla, whence the stimulus is conveyed to the salivary glands through the chorda tympani. Many of these drugs are eliminated with the saliva, and in some this elimination is attended with stomatitis. In the latter case the ptyalism may be secondary to the buccal affection. Jaborandi, which salivates within half an hour, and sometimes by the end of two minutes, causes no inflammation of the mucous membrane of the mouth, and doubtless acts directly upon the salivary glands. That it does not act through the nerves has been demonstrated by experiment. Salivation occurs after injecting pilocarpine into the blood, even when the nerves supplying the salivary glands have been previously divided. The same is said to be true of muscarin, physostigmine, and nicotine. Gold does not cause stomatitis, it is said, and it probably acts in a similar manner to the above. On the other hand, the salivation from mercury and copper is almost invariably accompanied with more or less inflammation of the mouth.

Of all forms of salivation, the one most frequently observed is that which occurs as a toxic manifestation of the constitutional action of mercury. That the stomatitis, which so commonly attends this form, plays a very important part in the etiology of the ptyalism, does not admit of doubt. As to the question whether it is the sole cause of the latter—whether without the stomatitis there would be no ptyalism, a number of well-authenticated cases, in which salivation occurred without any signs whatever of buccal inflammation, give a pretty definite answer. Hallopeau mentions a case observed by Fournier, in which salivation was produced by mercurial inunctions without the gums showing the least trace of inflammation. Similar cases have been observed by Fournier and others. Von Mering several times saw salivation produced in cats in five minutes after a hypodermic mercurial injection.

The opinion has been held that mercurial salivation is a dynamic effect of the mercury acting upon the general system, while others have maintained that it was due to an impression produced upon the sympathetic ganglia. The most rational explanation, however, is that it is the direct effect of the mercury contained in, and eliminated by, the saliva. That mercury is eliminated by the saliva there can no longer be any room for doubt. It has been verified repeatedly, and Bernatski has even succeeded in finding the metal in the saliva coming directly from Steno's duct. Doubtless both the ptyalism and the stomatitis may be due to the same irritating cause contained in the saliva, although the former would naturally be aggravated by the existence of the latter. All the facts seem to point to the presence of a corrosive poison in the secretion.

According to Ricord, the starting-point of this form of stomatitis is an area of inflammation just behind the last molar tooth, on the side on which the patient habitually sleeps, and this observation has also been repeatedly verified by Fournier. The natural inference is that the trouble begins where the saliva collects, and where the poison would therefore become concentrated. The well-known influence of the teeth in the production of mercurial gingivitis has an important bearing here. Edentulous individuals, such as infants and toothless old men, do not have inflammation of the gums when mercurialized. It would seem, therefore, that it is the collection and concentration of the poisoned saliva about the teeth that excites inflammation in the gums. It is a noteworthy fact, true as well of those who are exposed to the action of mercury by the nature of their occupation as of those who take it medicinally, that when particular attention is paid to the teeth, when they are often and carefully brushed, the individual most frequently escapes mercurial stomatitis. Indeed, it is a matter of every-day experience that patients undergoing mercurial treatment who are careful to keep the teeth clean, rarely show any oral effects whatever. Hutchinson says,[1] with regard to the so-called "mercurial teeth," that "the effects produced by mercury concern chiefly the enamel, although when severe, they affect the dentine also. The enamel is usually deficient, and the surface of the teeth is in varying degrees rugged, pitted, and dirty. The incisors and canines are usually affected, and not infrequently we see the enamel deficient on them all, below a line which crosses them at the same level. The appearance produced is much as if a line had been stretched horizontally across these teeth at about their middle." "The first molars" are "almost invariably affected" also. These appearances point pretty clearly to a corrosive effect, to which the teeth were subjected at an early age through the administration of mercury. The "line" of defective enamel mentioned corresponded, doubtless, in early childhood to the line of the gums, and to the part where the secretions and impurities of the mouth would be most apt to collect. Furthermore, it should be noted that of all modes of administration, that which brings the mercurial in direct contact with the mouth is most likely to cause stomatitis. Overbeck attributed the peculiar liability of calomel to produce salivation to the fact that, of all preparations, it was most apt to leave traces of the dose in the buccal cavity, where it would act topically after solution in the salivary fluid. In this connection we recall the observation of John Hunter, that every mercurial, when held long in the mouth, becomes sapid, showing that a solution takes place.

The inference seems unavoidable that the mercurial stomatitis, and to a certain extent also the ptyalism, are due to the elimination of the mercurial, which becomes corrosive immediately upon its escape from its organic connections. While circulating in the fluids of the body it is in intimate combination with the albumen, forming an albuminoid compound which almost assumes the character of the homogeneous substances of the body. But at the moment of elimination a noxious inorganic chemical substance is set free to work its deleterious effects. To account for the severity of these effects it must be remembered that there is a continual irrigation of the parts with the solution, and not a single application. And, furthermore, this solution will become more concentrated where the secretions are apt to collect, *i.e.*, at the borders of the teeth.

Of the conditions which are favorable to mercurial salivation, the most important depend upon the mode in which the mercury is introduced into the system. Generally speaking, those methods by which the drug is most rapidly introduced and absorbed are most likely to cause salivation. It is stated that it is oftenest observed after inunctions, fumigations, and the administration of calomel. It has been erroneously claimed that it was comparatively infrequent among workers in mercury. But, according to Kussmaul, though seldom so severe among them as when the drug is given therapeutically, it is

nevertheless always the most common of the symptoms of hydrargyrism. In the professional form of mercurialism the amount of mercury received into the economy is much smaller than when it is administered as a drug, and it is introduced more gradually. Hence acute toxic manifestations, such as ptyalism and stomatitis, are not often severe, while the constitutional disturbances are commonly more marked than in patients who are mercurialized therapeutically.

The dose necessary to produce mercurial salivation varies according to individual predisposition. Some individuals are singularly susceptible. Ricord speaks of a patient in whom one grain of calomel was sufficient to cause salivation. Trousseau saw a violent case follow a single vaginal injection of a solution of corrosive sublimate 3 parts in 5,000 parts of warm water. Breschet observed a similar effect in a woman the morning after the vaginal portion of the cervix had been cauterized with the acid nitrate of mercury. Gubler saw severe stomatitis result from a single mercurial friction to the abdomen of a woman suffering with puerperal peritonitis. Christison reported cases in which salivation followed, in one instance the administration of two grains of calomel, and in another the inunction of two drachms of mercurial ointment. On the other hand, cases are met with where prolonged exhibition of mercury in considerable doses fails to produce the slightest effect in the mouth. Hallopeau refers to a case in which a patient, who had been treated for months with mercurial inunctions without salivation, afterward had a stomatitis in consequence of a single local application of mercurial ointment for pediculi pubis. As a rule, women are more susceptible than men, and pregnant women are especially liable to it. Exposure to cold, when the system is under the influence of mercury, will often provoke or precipitate an attack of salivation. The influence of disease of, or neglect in cleansing, the teeth has already been referred to. The fact that a patient has previously been salivated appears to render the person more susceptible to a subsequent attack, perhaps for the reason that a certain amount of mercury still lingers in the system. Under certain provocations this residual mercury may give rise to ptyalism long after the use of mercury has been stopped. Kussmaul cites the case of a woman who had a sudden attack of salivation, without stomatitis, in connection with a severe frontal headache. The woman was pregnant, and her condition may have had something to do with the causation of the salivary flux; but it was discovered that at this time both the saliva and the urine contained mercury, though it was known that shortly before the attack the drug was not present. The patient had been a worker in quicksilver four years before, and had suffered severely during her employment from mercurialism with stomatitis. Other observers also have testified to the fact that salivation may occur at long intervals after exposure to mercury, whether professionally or medicinally; sometimes after exposure to cold; occasionally after the administration of certain drugs (especially the iodide of potassium), in connection with commencing gestation or with some nervous affection.

Thanks to the more conservative and rational treatment of syphilis now generally pursued, mercurial salivation is far from being the common malady it was in former times. Instead of being regarded as a necessary accompaniment of the cure in every case of syphilis, it has now, among the best practitioners, become an accident of exceptional occurrence. How important was the rôle that salivation formerly played in the treatment of syphilis appears from the following aphorisms of Boerhaave:

"1468. To procure it, drench the patients for several days with large quantities of ptisan.

"1469. Next give a small dose of calomel every two hours.

"1470. When the breath begins to be fetid, the gums are painful, the teeth seem to grow longer, examine whether it be proper to continue, to stop, or to check the symptoms.

"1471. A salivation of three or four pounds a day is enough.

"1472. If less, it must be excited by mercury.

"1473. If more abundant, it must be restrained by emollient clysters, purges, sudorifics.

"1476. This treatment should be kept up till the symptoms have entirely ceased, usually thirty-six days.

"1477. Afterward, for thirty-six days more, give only very moderate doses of mercury, to maintain a slight salivation."

When a patient is about to be salivated with mercury the first thing noticed usually is a sense of dryness and a disagreeable metallic taste in the mouth. If the teeth are clashed together the patient is aware of a little tenderness. The gums have a grayish appearance, or are slightly reddened and swollen, and if pressed upon a little pus wells up between their border and the teeth. There is emitted from the mouth a more or less fetid odor. Soon the gums begin to recede from the teeth, and when the tongue touches the latter it seems to the patient as though they were elongated. The tenderness increases and is accompanied with some pain in the jaws. Meantime the saliva increases in quantity, collects in the mouth, and, because of its disagreeable taste, the patient is often impelled to spit. The inflammation increases and extends to the lips, cheeks, and tongue. Their surfaces are covered with a whitish or yellowish coating, and exhibit the prints of the teeth. The saliva becomes more copious, and, if the case is severe, dribbles from the mouth. The mucous membrane becomes ulcerated, and the ulcers are covered with pseudo-membrane. The ulceration extends superficially rather than in depth. The teeth become loose. The mouth is kept continually open, with the swollen tongue protruding, and over the lips and chin flows a constant stream of stringy saliva, sometimes tinged with blood. The quantity may become enormous. The stench becomes horrible, tainting the air of the whole apartment in which the patient is. The condition of the patient, if the malady is not arrested, grows more and more distressing. The teeth drop out; the swelling and pain, which may extend to the face and neck, continue to augment till the patient can neither masticate nor swallow; speech becomes impossible, and even respiration may be greatly impaired. Sometimes deep gangrenous ulcers form and the mucous membrane separates in large sloughs. Occasionally there is suppuration of the parotid or cervical glands; sometimes phlegmon of the cheeks or roof of the mouth occurs, or there is gangrenous inflammation of the tongue; finally cicatricial deformities may result, unless the patient, worn out by the intensity of the disease and the impairment of nutrition, sinks into a fatal collapse. Cases of such intensity as this are fortunately very rare. The recovery in most severe cases is slow. The swelling gradually diminishes, the ulcers slowly heal, and the teeth regain their solidity. For a long time, however, the mucous membrane of the mouth remains vulnerable, and slight irritations, such as may arise from the use of sharp or pungent articles of food and the like, will suffice to reawaken the stomatitis and produce again some degree of sialorrhœa with more or less fetor of the breath.

The first indication for treatment in all cases of salivation is to remove, if possible, the offending cause. If the ptyalism be the result of a reflex irritation originating in the buccal cavity, in the stomach, or in regions still more remote, the surest way to relieve the secondary affection is to allay the primary irritation. Where this is impracticable, as, for example, in pregnancy, we may avail ourselves of certain drugs, such as belladonna or duboisia, which have a controlling influence over the salivary secretion. In other cases the offending cause is located in the salivary glands or contained in the saliva. In salivation from mercury the ptyalism is doubtless partly due to the direct action of a corrosive mercurial upon the salivary glands, but chiefly to the stomatitis which is the effect of the same corrosive poison in the mouth.

As already intimated, mercurial salivation is at the present time regarded as an exceptional occurrence in the treatment of syphilis, and is usually the result either of neglect of proper precautions, or of an idiosyncrasy on the part of the patient. If the mercury is judiciously

administered, the teeth properly attended to, and exposure to sudden changes of temperature avoided, the patient will rarely complain of ptyalism or stomatitis, except in their incipient stages.

So soon as signs appear indicating that the gums are "touched," the mercury should be suspended. Unfortunately there are cases in which this does not suffice to arrest the progress of the malady. The mercury accumulated in the system continues for some time to be eliminated in the saliva in sufficient quantity to maintain or augment the local irritation. Therefore, when the latter does not quickly subside, measures should be taken both to hasten elimination and to divert it to other emunctory channels. At the beginning, a brisk purge is to be given, followed by a series of hot baths and the administration of diuretics. To the same end iodine or the iodide of potassium may be given, bearing in mind, however, that the first effect of these remedies, sometimes, is to aggravate the trouble, though they are afterward beneficial in limiting its duration. The use of iodine to arrest salivation was first recommended by Knod. It is given in doses of ten centigrammes (one and a half grain) per day, gradually increased to twice that amount, as in the following formula:

℞. Iodine .... 0.25 (gr. iijss.).
Alcohol .... 8.00 (ʒ ij.).
Dissolve and add cinnamon
water .... 80.00 (℥ ijss.).
Simple syrup .... 16.00 (ʒ ij.).
M. Dose, two to four teaspoonfuls.

To check the flow of saliva one one-hundredth of a grain of atropia may be injected hypodermically, and repeated according to the effect. The inflammation of the mouth must be combated by astringent or disinfectant washes, and by the local and internal use of the chlorate of potash. Mouth-washes of borax, alum, or tannin in honey or glycerine and water (seven or eight grains to the ounce), or tincture of myrrh (ʒ ij.–iv.) in water or infusion of cinchona (℥ iv.), serve a good purpose. The chlorate of potash may be used as a mouth-wash, dissolved in cold tea or in infusion of flaxseed, to which a small portion of dilute hydrocyanic acid or spirits of chloroform may be added. It should also be administered internally in doses of two or three grains every hour or two. Should ulceration or gangrene supervene, mouth-washes containing carbolic acid, Labarraque's solution, or the permanganate of potash are required.

Edward Bennet Bronson.

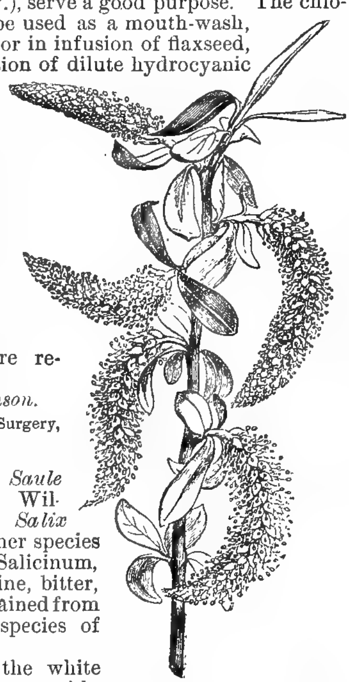

Fig. 3363.—Salix Alba, Staminate Branch. (Baillon.)

SALIX (U. S. Ph., *Saule blanc*, Codex Med.). Willow; "The bark of *Salix alba* Linn. and of other species of *Salix*." Salicin (Salicinum, U. S. Ph.), a crystalline, bitter, neutral substance, obtained from the bark of various species of Salix.

Salix alba Linn., the white willow, is a large tree with, when old, often a very thick, irregular trunk, dividing near the ground into several great limbs; branches numerous, ascending, rather close; twigs slender, brittle, with a light yellow or yellow-green bark, and white, rather brittle, soft wood; young shoots, buds, and the under surface of the leaves silky; leaves numerous, alternate, with minute stipules and short petioles; blade lanceolate, narrow, and very acute at the apex, white beneath, border finely serrate; flowers early, diœcious, in slender, weak spikes, each flower in the axil of a small bract; staminate flowers consist of two stamens, the pistillate of one one-celled, many-ovuled ovary; fruit dehiscent; two-valved, seeds silky. This willow has a very wide natural range, covering most of the temperate belt of the Old World; it has been also introduced into North America, where it is firmly naturalized. The bark of the small branches is officinal, and is collected with that of some other willows of similar appearance and properties.

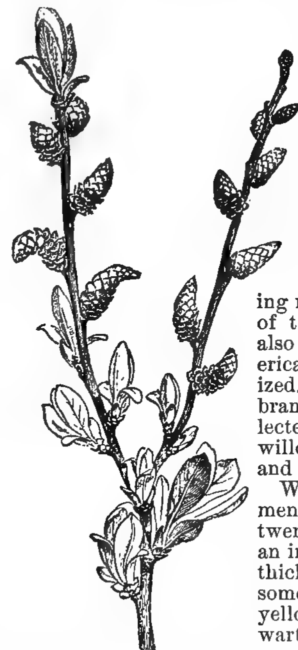

Fig. 3364.—Salix Alba, Pistillate Branch. (Baillon.)

Willow bark is "in fragments or quills, from one-twenty-fifth to one-twelfth of an inch (one to two millimetres) thick, smooth; outer surface somewhat glossy, brownish or yellowish, more or less finely warty; under the corky layer green; inner surface brownish-white, smooth, the fibres separating in thin layers; inodorous; bitter, and astringent." Willow is an old tonic and febrifuge, formerly official abroad, but dropped from most pharmacopœias since the easy preparation of salicin, which in a great measure took its place; neither is much used at present.

Fig. 3365.—Salix Alba, Fruit. (Baillon.)

Composition.—The bitter, crystalline, neutral principle, *salicin*, is the characteristic derivative of all the willows. It is easily prepared by exhausting the bark with water, precipitating tannin, etc., with litharge, evaporating and crystallizing out the salicin, which is then purified by resolution and the same process again. Salicin is colorless, odorless, but very bitter; it crystallizes in scales and needles; is permanent in the air; melts at 198° C. (388.4° F.); dissolves in twenty-eight parts of water and thirty of alcohol; sublimes and is entirely dissipated by heat; with concentrated sulphuric acid it forms a red solution. It is a glucoside; treated with diluted sulphuric or hydrochloric acid, or with a powerful galvanic current, it is decomposed, and saligenin and glucose are formed; by other methods of handling many interesting derivatives have been obtained; salicylous and salicylic acids, saliretin, helicin, helicoidin, etc. It has also been formed synthetically.

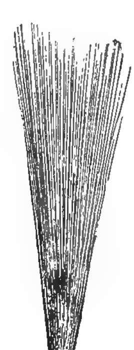

Fig. 3366.—Salix Alba, Seed. (Baillon.)

Action and Use.—As salicin is the only active principle, whatever value this bark has is due to it. Salicin itself, it must be confessed, is far from an energetic remedy—between two and three ounces have been taken with no marked effect. It appears to be decomposed in the blood into saligenine, salicylic acid, etc., and is eliminated from the kidneys as one or more of these products. Salicin has undoubted antipyretic power, although less than quinine or salicylic acid, its antiperiodic action is much less than

that of either of them; as a remedy in rheumatism, salicin has also been obliged to yield to the more useful salicylic acid. As a tonic, in small doses, it is occasionally used, but is far inferior to gentian or quinine. Four or five grams (ʒ j. ad ʒ jss.) may be given as a dose, and repeated every three hours; as a tonic one or two decigrams (gr. jss. ad iij.) is sufficient.

Allied Plants.—The genus comprises a hundred and sixty species; from twenty or more this substance has been obtained. The allied genus *Populus* has some salicin-yielding species, and others containing *populin*, which latter can be made to yield salicin itself by decomposition. The order, in its narrow sense, contains but these two genera.

Allied Drugs.—A number of plants in different orders yield also a little salicin, but not enough to make it their characteristic principle. The various tonics, of which Gentian, Columbo, Cinchona, etc., are examples, are also related, and the latter is doubly so as an antiperiodic. Other glucosides of mild or tonic qualities are *hesperidin*, from orange peel; *phloridzin*, from apple bark; *arbutin*, from several *Ericaceæ; æsculin*, from the horse-chestnuts, etc.

W. P. Bolles.

SALOL. Under the titles *salol* and *salicylate of phenol*, there has been recently proposed, for medicinal use, a body compounded of salicylic acid and carbolic acid (phenol), representing in its composition sixty per cent. of salicylic acid and forty per cent. of carbolic. Salol is a white crystalline powder, melting at 43° C. (110° F.) into a colorless, oily fluid. It is nearly insoluble in water, but dissolves in alcohol, ether, and fixed oils. From its insolubility in aqueous fluids it is practically tasteless in powder, but it has a faint aromatic smell.

Salol has been proposed as a substitute for the commonly used salicylate salts, on the grounds that it is equally, at least, effective as a medicine, while at the same time, in medicinal doses, it is much less deranging to digestion on the one hand, and less productive of constitutional toxic effects on the other. It is said of this substance that it is insoluble in the fluids present in the stomach—whence the lack of gastric derangement in its employment—but suffers solution by chemical decomposition in the small intestine through the action of the pancreatic juice, resolving into salicylic acid and carbolic acid (phenol). Constitutionally, so far as reported, salol, in ordinary dosage, has produced little disturbance beyond an occasional and trifling ringing in the ears. In experimenting, however, with a dosage exceeding 6.00 Gm. (about a drachm and a half) distributed over the twenty-four hours, toxic symptoms have been observed. Salol, taken internally, imparts to the urine of the subject the peculiar coloration seen after ingestion of carbolic acid, a phenomenon that may persist for several days after discontinuance of the medicine. The average medicinal dose of salol for an antirheumatic or antipyretic effect is 2.00 Gm. (about thirty grains), given twice, or possibly thrice, daily. A dosage reaching 8.00 Gm. (about two drachms), in the course of a day, was followed, in one instance, by severe vomiting, gastralgia, and tinnitus. Salol may be taken dry upon the tongue, in powder, the dose to be washed down with a little water, or may be conveniently administered in pill-form.

Edward Curtis.

SALT SULPHUR SPRINGS. *Location and Post-office*, Salt Sulphur Springs, Monroe County, W. Va.

Access.—By the Chesapeake & Ohio Railway to Fort Spring, two hundred and forty-four miles west from Richmond, Va., thence by stage fifteen miles south to the springs. Stages meet the C. & O. Railway trains at Fort Spring.

Therapeutic Properties.—The name Salt Sulphur would imply the presence of an appreciable amount of sodium chloride. This is not the case, so that the name is not appropriate. They are rather alkaline sulphur waters, purgative and alterative. Taken internally or employed as baths, they are effective in chronic diseases of the digestive organs, bladder, liver, and kidneys, and I am informed of their utility in chronic neuralgias. The iodine spring is indicated in syphilitic and scrofulous disorders.

Analysis.—One pint contains:

This resort, possessing the Iodine, Salt Sulphur, and Sweet Sulphur Springs, is beautifully situated in a valley north of Peter's Mountains, Alleghany range, on the banks of Indian Creek, at an elevation of 2,000 feet above sea-level. The surrounding views of mountains and hills are charming, and the climate is delightful. The hotel buildings are built principally of brick and stone, the largest containing seventy-two rooms, with wide piazzas, and surrounded by a beautiful lawn. An elegant ballroom, a billiard-room, tennis courts, bowling alleys, etc., furnish amusement for the guests.

G. B. F.

SALZUNGEN is a spa in Sachsen-Meiningen, Thüringen, lying in the valley of the Werra, at an altitude of about 820 feet above the level of the sea. There are several salt-wells here, the composition of one of which, the Bernhardsbrunnen, is as follows.

One litre contains:

	Grammes.
Sodium chloride	260.76419
Potassium chloride	0.32566
Magnesium chloride	0.20179
Calcium chloride	0.78266
Magnesium bromide	0 01218
Sodium sulphate	1.25679
Calcium sulphate	3.34013
Magnesium sulphate	0.19408
Calcium carbonate	0.05199
Magnesium carbonate	0.00188
Ferrous carbonate	0.01318
Silicic acid	0.00259
Total	266.94712

There are also traces of iodine, lithium, aluminium, and manganese. There is some carbonic acid gas. When employed internally, the water is usually diluted with milk or whey. Baths, douches, local compresses, and inhalations are made use of.

These waters are employed in the treatment of catarrhal troubles of the respiratory mucous membranes, anæmia, and scrofulous affections of the joints, bones, glands, and skin.

The season extends from the middle of May to October. A course of treatment lasts from two to three weeks.

T. L. S.

SAN ANTONIO. The accompanying chart, obtained from the Chief Signal Office, represents the climate of the city of San Antonio, Tex., a town of twenty thousand inhabitants, lying at an elevation of six hundred and fifty-six feet above sea-level, and situated two hundred and forty-five miles to the north of Brownsville, and one hundred and thirty miles from the coast of the Gulf of Mexico. Its climate may be regarded as typical of that of the inland and moderately elevated portion of Southern

Texas. What this climate is may be seen fairly well from a study of the chart (an explanation of which will be found on pages 189–191 of vol. ii.). The reader's attention is especially called to the general mildness of temperature during the winter season, which, *so far as shown by the figures of Column AA,* is seen to be nearly as warm as the autumn at New York City. Columns E, F, and J show, however, a great range of possible extremes at San Antonio, and Table F, in the article entitled Colorado Springs (vol. ii., p. 238), shows that the average daily range of temperature is thirty-three per cent. higher at San Antonio than at New York City. As a rule the atmosphere is remarkably still at San Antonio, and in this respect this station even surpasses that of Little Rock, Ark.; but San Antonio is a Texan town, and Texas, with its ill-famed "northers," is that part of the United States which is most liable to great and very sudden falls of temperature upon the supervention in winter of a northerly wind. Column K shows us that the San Antonio climate is moderately dry; column O, that the winter rainfall is very light. *H. R.*

SANDAL WOOD, OIL OF (*Oleum Santali,* U. S. Ph.; Br. Ph.; *Santal citrin,* Codex Med.; yellow (or white) sandal wood).

Santalum album Linn., order Santalaceæ, is a small East Indian tree, whose fragrant wood has made it a highly esteemed plant from the most remote time. It has a slender habit, with opposite branches, and smooth, light-green, opposite, lanceolate leaves; inflorescence small, close, pyramidal, paniculate cymes; flowers minute, perfect; the perianth is single, bell-shaped, four- or five-lobed, at first yellow, afterward purplish; stamens opposite, arising from the throat of the corolla, and separated by a series of alternate scales; pistil one, ovary one-celled, with central placentæ and three or four naked, pendulous ovules; fruit one-seeded, about as large as a currant. This tree is a native of India, and of some of the islands of the Indian Archipelago. It is also cultivated, the property of the government or protected by the authorities, in most localities; in others it has been exterminated.

Collection.—The logs are felled, cut into short lengths, and then left on the ground for several months, while the white ants gnaw away the alburnum, or white outside zone, and leave the valuable heart-wood perfectly cleaned. This is then cut and made into various articles of cabinet work or convenience, the chips and coarser portions being put into the still for the extraction of the oil. A considerable amount of the wood is exported to England and Germany, where a high grade of oil is distilled. The root is also dug up and used.

This is a compact, heavy, porous wood, of pleasant aromatic odor, pungent, astringent taste, and yellowish-brown, variegated color. The oi , of which it contains from one to three per cent., is a thickish, pale yellow liquid of agreeable, aromatic odor, pungent, spicy taste, neutral reaction, and specific gravity of 0.945.

As a perfume, etc., but not generally as a medicine, sandal wood has been used for more than a thousand years. It was known in Europe some eight hundred years ago, and it has always been a costly perfume. Its modern employment in gonorrhœa, etc., is not more than a generation old.

Of the different trade varieties, that from the East Indies is most highly prized, that of the West Indies and South America the least. There may not be so very much difference in their medical properties.

Action and Use.—Sandal wood oil resembles copaiba in many respects, as well as the terebinthinous oils in general. It is readily absorbed and pretty promptly eliminated, appearing both in the urine and in the exhalation from the lungs. It is slightly astringent, and fre-

quently followed by discomfort in the stomach and dryness of the throat; occasionally it causes vomiting and colic. Disagreeable eructations and its taste are complained of by some patients, but on the whole it is less unpleasant than copaiba. Its elimination by the kidneys, which is sometimes accompanied by a feeling of tension there, changes the odor of the urine, and causes it to become cloudy with acid, in the same way as copaiba; alcohol, by clearing up this cloudiness, which is caused by a resinous precipitate, will distinguish it from albumen. The sandal wood products in the urine exert a beneficial action upon vesical, and especially gonorrhœal, inflammations, equal to, if not better than, that of copaiba or cubebs, for which it is an efficient and rather more elegant substitute. It is especially serviceable in recent acute cases with considerable discharge.

Administration.—This is simple enough. Dropped upon sugar, or shaken with mucilage, it can be easily taken by those who do not mind its disagreeable taste, but probably more than nine-tenths of it is given in gelatine capsules, where it is often mixed with copaiba or cubebs. Dose, from five to twenty drops—ten is a good average—four or five times a day. It should be continued a week or so after the symptoms have disappeared.

Allied Plants.—There are eight known species of *Santalum*, all closely related. They are inhabitants of India, Australia, and of many of the Pacific Islands; all are fragrant, and perhaps others than *S. album* may contribute to the yield of East Indian sandal wood. *S. Yasi* Seem, of the Fiji Islands, *S. Freycinetianum* Gaudich, and *S. Pyrularium* Gray, of the Sandwich Islands, and several species in Australia, furnish both wood and oil. The order is a rather small one, comprising some two hundred species, mostly shrubs or trees, and often root-parasites. The source of West Indian and South American "Oil of Sandal" is not known. It resembles in its odor and taste the East Indian oil, but is cruder and less agreeable. It is very much cheaper, and is the kind usually dispensed for medicine, the other being reserved for perfumery.

Allied Drugs.—From a medical point of view Copaiba and Cubebs are most nearly related to the subject of this article. As an astringent of the intestinal and urinary mucous membranes it may be compared with Turpentine, to which it is inferior; as an alterative to bronchial secretion, for which purpose it is sometimes given, Grindelia is superior; in cystitis, etc., it is comparable with the balsams, as well as Buchu, Uva Ursi, etc. The red saunders, or red sandal wood, resembles this product only in name.

W. P. Bolles.

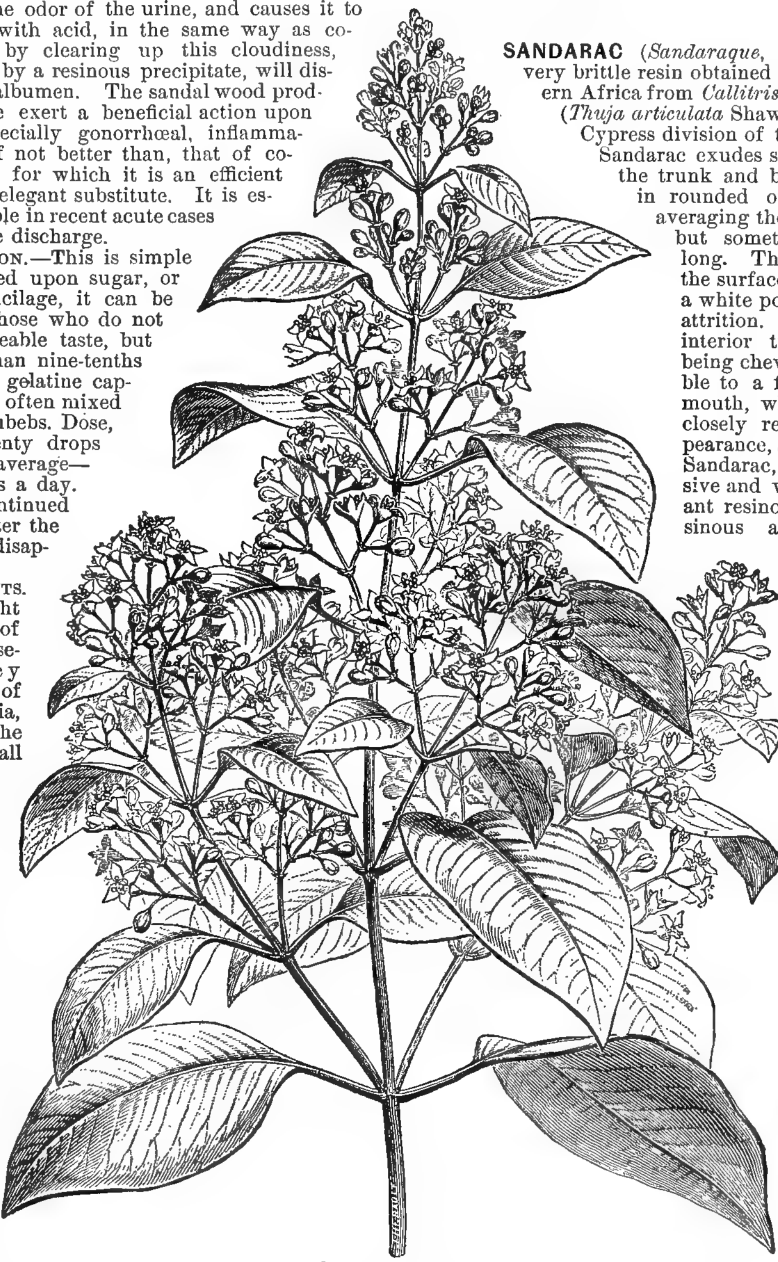

Fig. 3367.—Flowering Branch of Sandal Wood Tree, about Natural Size. (Baillon.)

SANDARAC (*Sandaraque*, Codex Med.). A very brittle resin obtained in tears in Northern Africa from *Callitris quadrivalvis* Vent. (*Thuja articulata* Shaw), a member of the Cypress division of the order *Coniferæ.* Sandarac exudes spontaneously from the trunk and branches, and dries in rounded or irregular drops averaging the size of small peas, but sometimes larger and long. The tears are dull on the surface and covered with a white powder produced by attrition. Fracture glassy, interior transparent. Upon being chewed the tears crumble to a fine powder in the mouth, while Mastic, which closely resembles it in appearance, softens. Powdered Sandarac, which is non-adhesive and white, with a pleasant resinous odor, and a resinous and bitter taste, is called "Pounce," and was formerly used to rub over the surface of paper where an erasure had been made, to prevent the ink from running when it was written over again. Sandarac is not used at present in medicine. This resin is a compound one, consisting of at least two, having different degrees of solubility in alcohol, ether, etc.

Allied Plants, Etc.—See Turpentine.

W. P. Bolles.

SANDEFJORD is a Norwegian health-resort, pleasantly situated on a fjord at a short distance from the sea. In addition to the sea-bathing, therapeutic use is made of the several mineral springs here found. Sea-mud, containing sulphur, iron, and common salt, is used in the form of baths, poultices, and as a local application applied with friction.

Sandefjord enjoys considerable reputation as a resort for those suffering from chronic rheumatism, neuralgia, nervous prostration, chronic joint diseases and other so-called scrofulous affections. The season extends over

the months of June, July, and August. A course of treatment occupies the usual time of three or four weeks.

The following is the composition of the three principal springs, computed in grammes per litre :

	Alum-iron Spring (Analysis of Hiortdahl, 1886).	Saline Spring (Hiortdahl, 1885).	Iron-saline sulphur Spring (A. Strecker, 1854).

T. L. S.

SAN DIEGO. [For a detailed explanation of the accompanying chart and suggestions as to the best method of using it, see the general article on Climate.]

The city of San Diego, California, lies upon the sloping northeast shore of a land-locked bay five and a half miles long, twenty square miles in area, and twenty-three feet deep on its bar at low water, constituting a harbor which, by competent authority, has been pronounced to be, "with the single exception of San Francisco, perhaps the best from Callao to Puget Sound" (General Emory, of U. S. Engineers, quoted by a writer in the *New York Times* of May 9, 1886). The town is the most southerly of any in California, lying in the extreme southwestern corner of the State, only fifteen miles distant from the Mexican border, and its latitude is almost precisely the same as that of Yuma, Arizona, from which it is distant about one hundred and fifty miles in a westerly direction. From San Francisco it is distant nearly five hundred miles in a direction S.E. by S. The population in 1880 was less than three thousand; it is now (1887) estimated at about seven thousand. The slope of the hill upon which the town is built is three hundred feet to the mile; hence the natural facilities for drainage must be good. Concerning the soil, I possess no information save that the writer in the *New York Times*, already cited, states that "there is little mud and the ground dries in a few hours after the heaviest rain." The water-supply of the town was formerly deficient, but Dr. Chamberlain, in a paper read before the New York Academy of Medicine in October, 1886, says of this defect that it is one which he believes is soon to be remedied. There are good hotels at San Diego. As may be seen from the chart opposite, the winter climate of San Diego, so far as mean temperature is concerned, is about the same as that of Los Angeles, but the daily range is much less than at Los Angeles, and a decidedly greater equability of temperature throughout the year is found at San Diego, on the coast, than at Los Angeles, amông the hills and seventeen miles back from the coast. San Diego has a less rainfall, but a more cloudy sky and markedly more humid atmosphere than has Los Angeles. In point of windiness the two places are almost precisely alike in winter; very similar, indeed, throughout the year. In regard to the frequency of occurrence of fogs at San Diego, I find two contradictory statements: that of the writer in Appleton's "Handbook of Winter Resorts" (1886–1887), who says of San Diego that "there is no fog, as in Santa Barbara and more northern latitudes, and very little moisture in the air," and that of Dr. Chamberlain (loc. cit.), who tells us that the local climate of San Diego is "unsurpassed in the matter of temperature," but is damp; for while the "rains are few," the "fogs are frequent." Dr. Chamberlain also speaks of the fogs at Santa Barbara. Dr. H. S. Orme, president of the California State Board of Health, in his interesting pamphlet entitled "The Climatology and Diseases of Southern California," tells us that "from the time of the first rains the belt of country next the coast is bathed in an atmosphere which is tolerably moist," and that "at a distance of a few miles inland the relative humidity increases, not because there is more moisture, but because the temperature is apt to range lower." In this belt, he tells us, "the fogs are heaviest and the deposition of dew is greatest;" while beyond it, "as the distance from the coast increases, the relative humidity decreases until, at the crest which separates the Pacific slope from the Great Basin the air throughout the year is dry, pure, and invigorating." The limits of the belt of country characterized by an especially frequent occurrence of fogs, and by greater relative humidity than elsewhere throughout the Southern California region, cannot be very accurately defined; but to the seaward it is in general bounded and defined by a line drawn parallel to and at a distance of five miles back from the coast. Probably it is only close to its seaward border that this district is damper than the coast belt itself. Its inland border I can by no means determine, for while Dr. Lindley (see his paper quoted in article Los Angeles and Pasadena) speaks of an elevation of one thousand feet as the inland limit of the region wherein fogs "sometimes come in from the sea," and the atmosphere "during the winter months is somewhat moist," we see from the chart of Los Angeles, a point only seventeen miles back from the sea, and 283 feet above its level, that the relative humidity in winter is decidedly less than in summer; while a comparison of column J in the Los Angeles chart with the same column in the San Diego chart shows that, month by month throughout the entire year, the relative humidity of Los Angeles is very markedly less than that of San Diego, a place not lying within this belt of especially great humidity, frequent fogs, and heavy dewfall, but upon the coast which, according to Dr. Orme, is drier and less liable to fogs than this belt, beginning "at a distance of a few miles inland."

The paramount importance of a careful study of each "climat de localité" in Southern California has already been urged in the article on Los Angeles and Pasadena, is well recognized by all authorities on this subject whom I have consulted, and is probably exemplified before the eyes of the reader who has followed us through what has just been said respecting the somewhat misty limits of this belt of winter dampness and spring fogs.

A brief and necessarily general discussion of the climate of Southern California taken as a whole, and of its undoubtedly great adaptation to the purpose of a health region for the resort of phthisical and other invalids during the winter season, or during the entire year, has already been presented in the article entitled "Los Angeles and Pasadena." To what is said in that article, and in particular at its close (page 582 of vol. iv.), I have nothing to add, merely repeating here, in slightly different form, what I have said before, viz., that for many invalids Southern California is not only a good winter residence, but is a health-giving and health-restoring home for residence all the year round; and this in no small

Climate of San Diego, Cal.—Latitude 32° 43′, *Longitude* 117° 10′.—*Period of Observations, November* 1, 1871, to *December* 31, 1883.—*Elevation of Place of Observation above Sea-level*, 49 *feet.*

degree by reason of the very considerable varieties of climate which are therein to be found comprised within a comparatively limited area of territory.

In conclusion, and as emphasizing the equability of the climate of San Diego, the place now under our special consideration, and, as illustrating its immunity from even occasional extremes of heat and of cold, I quote the following data, derived from Appleton's "Handbook of Winter Resorts," from Dr. Orme's pamphlet, and from the letter to the *New York Times* of May 9, 1886, already quoted above. During the ten years 1876 to 1885 the mercury at San Diego rose above 80° F. on only one hundred and twenty days (*i.e.*, on an average but twelve times in each year); and it went above 95° F. on only six days. During the same period it fell below 40° F. on only ninety-three days, an average of but nine days in each winter; and on no day did it remain below 40° F. more than two or three hours, and this between midnight and daylight. It fell below 35° F. on six occasions only throughout the whole period of ten years, and never once fell below 32° F. Says the *Times* correspondent, commenting upon these figures: "There is therefore no such difference between summer and winter, or between day and night, as to prevent one from wearing the same clothing and sleeping under the same cover all the year round."

During the year 1880 the thermometer at San Diego rose to 90° F. only six times, while at Los Angeles this temperature was reached fourteen times (Dr. Orme, *op. cit.*).
